Masses and Compositions of the Twenty Commonly Occurring Amino Acid Residues

Name	Abbreviations		Residue Structure	Average Mass[a]	pK_a of Ionizing Side Chain[b]	Occurrence in Proteins (%)
Alanine	Ala	A		71.0788	—	8.3
Arginine	Arg	R		156.1876	~12	5.7
Asparagine	Asn	N		114.1039	—	4.4
Aspartic Acid	Asp	D		115.0886	3.9–4.0	5.3
Cysteine	Cys	C		103.1448	9.0–9.5	1.7
Glutamic Acid	Glu	E		129.1155	4.3–4.5	6.2
Glutamine	Gln	Q		128.1308	—	4.0
Glycine	Gly	G		57.0520	—	7.2
Histidine	His	H		137.1412	6.0–7.0	2.2
Isoleucine	Ile	I		113.1595	—	5.2
Leucine	Leu	L		113.1595	—	9.0
Lysine	Lys	K		128.1742	10.4–11.1	5.7
Methionine	Met	M		131.1986	—	2.4
Phenylalanine	Phe	F		147.1766	—	3.9
Proline	Pro	P		97.1167	—	5.1
Serine	Ser	S		87.0782	—	6.9
Threonine	Thr	T		101.1051	—	5.8
Tryptophan	Trp	W		186.2133	—	1.3
Tyrosine	Tyr	Y		163.1760	10.0–10.3	3.2
Valine	Val	V		99.1326	—	6.6

[a] The molecular mass of a normally terminated and unmodified peptide or protein may be calculated by summing the masses of the appropriate amino acid residues and adding the masses of H and OH for the N and C termini, respectively. In cases where cysteines are linked by disulfide bridges, the mass of 2 hydrogen atoms should be subtracted for each disulfide bridge in the molecule.

[b] These values are included for anyone wishing to make approximate isoelectric point determinations based on protein composition. Values for the terminal residues depend on the identity of the residue: α-amino, pK_a 6.8–8.0; α-carboxyl, pK_a 3.5–4.3.

Table of Contents, Volumes 1 and 2

i Foreword

iii Preface

vii Contributors

1 Strategies of Protein Purification and Characterization

1.1 Overview of Protein Purification and Characterization
1.2 Strategies for Protein Purification
1.3 Protein Purification Flow Charts

2 Computational Analysis

2.1 Computational Methods for Protein Sequence Analysis
2.2 Hydrophobicity Profiles for Protein Sequence Analysis
2.3 Protein Secondary Structure Prediction
2.4 Internet Basics
2.5 Sequence Similarity Searching Using the BLAST Family of Programs

3 Detection and Assay Methods

3.1 Spectrophotometric Determination of Protein Concentration
3.2 Quantitative Amino Acid Analysis
3.3 In Vitro Radiolabeling of Peptides and Proteins
3.4 Assays for Total Protein
3.5 Kinetic Assay Methods
3.6 Biotinylation of Proteins in Solution and on Cell Surfaces

4 Extraction, Stabilization, and Concentration

4.1 Overview of Cell Fractionation
4.2 Purification of Organelles from Mammalian Cells
4.3 Subcellular Fractionation of Tissue Culture Cells
4.4 Desalting, Concentration, and Buffer Exchange by Dialysis and Ultrafiltration
4.5 Selective Precipitation of Proteins

5 Production of Recombinant Proteins

5.1 Production of Recombinant Proteins in *Escherichia coli*
5.2 Selection of *Escherichia coli* Expression Systems
5.3 Fermentation and Growth of *Escherichia coli* for Optimal Protein Production
5.4 Overview of the Baculovirus Expression System
5.5 Protein Expression in the Baculovirus System
5.6 Overview of Protein Expression in *Saccharomyces cerevisiae*

continued

5.7 Overview of Protein Expression in *Pichia pastoris*
5.8 Culture of Yeast for the Production of Heterologous Proteins
5.9 Overview of Protein Expression by Mammalian Cells
5.10 Production of Recombinant Proteins in Mammalian Cells

6 Purification of Recombinant Proteins

6.1 Overview of the Purification of Recombinant Proteins Produced in *Escherichia coli*
6.2 Preparation of Soluble Proteins from *Escherichia coli*
6.3 Preparation and Extraction of Insoluble (Inclusion-Body) Proteins from *Escherichia coli*
6.4 Overview of Protein Folding
6.5 Folding and Purification of Insoluble (Inclusion-Body) Proteins from *Escherichia coli*
6.6 Expression and Purification of GST Fusion Proteins
6.7 Expression and Purification of Thioredoxin Fusion Proteins

7 Characterization of Recombinant Proteins

7.1 Overview of the Characterization of Recombinant Proteins
7.2 Determining the Identity and Purity of Recombinant Proteins by UV Absorption Spectroscopy
7.3 Determining the Identity and Structure of Recombinant Proteins
7.4 Transverse Urea-Gradient Gel Electrophoresis
7.5 Analytical Ultracentrifugation
7.6 Determining the CD Spectrum of a Protein
7.7 Determining the Fluorescence Spectrum of a Protein
7.8 Light Scattering
7.9 Measuring Protein Thermostability by Differential Scanning Calorimetry

8 Conventional Chromatographic Separations

8.1 Overview of Conventional Chromatography
8.2 Ion-Exchange Chromatography
8.3 Gel-Filtration Chromatography
8.4 Hydrophobic-Interaction Chromatography
8.5 Chromatofocusing
8.6 Hydroxylapatite Chromatography

9 Affinity Purification

9.1 Lectin Affinity Chromatography
9.2 Dye Affinity Chromatography
9.3 Affinity Purification of Natural Ligands
9.4 Metal-Chelate Affinity Chromatography
9.5 Immunoaffinity Chromatography
9.6 Purification of Sequence-Specific DNA-Binding Proteins by Affinity Chromatography
9.7 Purification of DNA-Binding Proteins Using Biotin/Streptavidin Affinity Systems

BCU IAS / CENTRAL UNIVERSITY LIBRARY

10 Electrophoresis

10.1 One-Dimensional SDS Gel Electrophoresis of Proteins
10.2 One-Dimensional Isoelectric Focusing of Proteins in Slab Gels
10.3 One-Dimensional Electrophoresis Using Nondenaturing Conditions
10.4 Two-Dimensional Gel Electrophoresis
10.5 Protein Detection in Gels Using Fixation
10.6 Protein Detection in Gels Without Fixation
10.7 Electroblotting from Polyacrylamide Gels
10.8 Detection of Proteins on Blot Membranes
10.9 Capillary Electrophoresis of Proteins and Peptides
10.10 Immunoblot Detection
10.11 Autoradiography
10.12 Overview of Digital Electrophoresis Analysis

11 Chemical Analysis

11.1 Enzymatic Digestion of Proteins in Solution
11.2 Enzymatic Digestion of Proteins on PVDF Membranes
11.3 Digestion of Proteins in Gels for Sequence Analysis
11.4 Chemical Cleavage of Proteins in Solution
11.5 Chemical Cleavage of Proteins on Membranes
11.6 Reversed-Phase Isolation of Peptides
11.7 Removal of N-Terminal Blocking Groups from Proteins
11.8 C-Terminal Sequence Analysis
11.9 Amino Acid Analysis
11.10 N-Terminal Sequence Analysis of Proteins and Peptides

12 Post-Translational Modification: Glycosylation

12.1 Overview of Glycoconjugate Analysis
12.2 Metabolic Radiolabeling of Animal Cell Glycoconjugates
12.3 Inhibition of N-Linked Glycosylation
12.4 Endoglycosidase and Glycoamidase Release of N-Linked Oligosaccharides
12.5 Detection of Glycophospholipid Anchors on Proteins

13 Post-Translational Modification: Phosphorylation and Phosphatases

13.1 Overview of Protein Phosphorylation
13.2 Labeling Cultured Cells with $^{32}P_i$ and Preparing Cell Lysates for Immunoprecipitation
13.3 Phosphoamino Acid Analysis
13.4 Detection of Phosphorylation by Immunological Techniques
13.5 Detection of Phosphorylation by Enzymatic Techniques
13.6 Production of Antibodies That Recognize Specific Tyrosine-Phosphorylated Peptides
13.7 Assays of Protein Kinases Using Exogenous Substrates
13.8 Permeabilization Strategies to Study Protein Phosphorylation

BCIT LIBRARY - BRITISH COLUMBIA INSTITUTE OF TECHNOLOGY

14 Post-Translational Modification: Specialized Applications

14.1 Analysis of Disulfide Bond Formation
14.2 Analysis of Protein Acylation
14.3 Analysis of Protein Prenylation and Carboxyl-Methylation

15 Chemical Modification of Proteins

15.1 Modification of Cysteine
15.2 Modification of Amino Acids

16 Mass Spectrometry

16.1 Overview of Peptide and Protein Analysis by Mass Spectrometry
16.2 Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Analysis of Peptides

17 Structural Biology

17.1 Overview of Protein Structural and Functional Folds
17.2 Overview of Macromolecular Electron Microscopy
17.3 Principles of Macromolecular X-Ray Crystallography
17.4 Crystallization of Soluble Macromolecules

18 Preparation and Handling of Peptides

18.1 Introduction to Peptide Synthesis
18.2 Synthesis of Multiple Peptides on Plastic Pins
18.3 Synthetic Peptides for Production of Antibodies that Recognize Intact Proteins

BCU IASLIC CENTRAL UNIVERSITY LIBRARY

FOREWORD

Over the past five to ten years we have witnessed a revolution in biological research which is fueled by our increasing capacity to decipher biological information of three types: the digital information embedded in DNA with its four-letter alphabet; the three-dimensional information represented by proteins, the major executors of biological function; and the four-dimensional information of complex biological systems and networks representing the temporal and spatial interaction of multiple components. The analysis of complex systems and networks in their entirety is essential for scientists to understand the molecular basis of fascinating processes such as growth, development, and differentiation, and to extract the biological meaning of emergent properties such as consciousness, memory, and the ability to learn which evolved over billions of years.

Not surprisingly, the linear nucleotide sequence in DNA has been the first type of information to be deciphered. Large-scale genetic mapping and DNA sequencing rapidly generate enormous amounts of biological information. In many ways, programs such as the human genome project represent some of the earliest attempts to understand biological complexity. Successful completion of the human genome and similar projects will pose the challenge of interpreting the information contained in billions of nucleotides and of explaining how the interplay of the products of perhaps 100,000 genes results in the myriad of biological phenotypes. Meeting these challenges will require new interdisciplinary strategies which draw from the expertise of scientists from disciplines as different as molecular biology, biochemistry, engineering, chemistry, applied mathematics, and computer science.

Protein science is central to such integrated strategies. Separation of proteins from complex mixtures, followed by structural and functional analyses, control of protein function, post-translational processing, and modification and formation of macromolecular complexes of proteins and other biomolecules are but a few examples of topics which are essential for all those scientists who attempt to interpret the linear DNA sequence in terms of the three- and four-dimensional information of complex biological systems and networks. The following chapters detail the necessary protocols for this endeavor, provided by experts in experimental protein science.

Two attractive features set this manual apart from other collections of research protocols. First, *Current Protocols in Protein Science* will be continuously updated and expanded by quarterly additions to the core edition. Secondly, this volume as well as the updates are also available on CD-ROM. Numerous cross-references within the manual by hypertext links, context based searching, and provisions for making individualized notebooks containing frequently used protocols are attractions of the CD-ROM version which are in tune with the increasing dependence on computers in biological research laboratories.

Protein science is a diverse, experimentally challenging, and rapidly evolving discipline. This book provides expert guidance in experiment design and execution and promises to remain up-to-date, in contents and in format, for many years to come.

BCU IAS / CYFRA-UNIVERSITY LIBRARY

PREFACE

Proteins are like people: they are highly diverse, with very few traits shared by the entire population. Even close relatives often have very different structural (physical) characteristics and behave quite differently. This heterogeneity presents challenges for scientists interested in studying protein structure and function. The need for a readily accessible, updatable reference for protein methods has grown in tandem with the ongoing protein science renaissance driven by advances in molecular biology, genetics, structural biology, and related disciplines. Using recombinant methods, it is now practical to overexpress both normal and reengineered forms of a protein and to create chimeric proteins with unique new properties. The ability to express proteins usually found in low abundance at high levels and to manipulate their amino acid sequences provides unprecedented opportunities to study a vast array of proteins and their associated biological processes (both in vitro and in vivo). The combination of biochemical, biophysical, and high-resolution structural analyses of proteins with manipulation of the associated genes (in cultured cells or an entire mammalian organism) has already led to spectacular advances in many areas of biotechnology and molecular medicine.

Because proteins are so diverse, a wide range of techniques must often be considered and tested empirically for a particular protein, and each researcher's arsenal must include both recent innovations and techniques that have been used for many years. Moreover, methods appropriate for purifying and initially characterizing the protein(s) associated with a biological activity of interest are often not suitable for analyzing the corresponding overexpressed recombinant protein. This manual includes both specific detailed protocols as well as strategies for adapting methods to particular projects at hand. It is designed to meet the needs of scientists with little prior experience of protein isolation and characterization, including graduate students and scientists trained in other biological disciplines. At the same time, the broad range of techniques presented here should ensure that even seasoned experts will find new and useful approaches and will benefit from the manual's convenient compilation of standard information and methods that typically must be culled from many sources.

The quarterly updating service will allow ongoing expansion of the core volume to include chapters covering critical topics that were deferred due to initial space limitations and to keep pace with the "cutting edge" of developments in this fast-moving field.

HOW TO USE THIS MANUAL

Format and Organization

This publication is available in both looseleaf and CD-ROM format. For looseleaf purchasers, a binder is provided to accommodate the growth of the manual via the quarterly update service. The looseleaf format of the binder allows easy insertion of new pages, units, and chapters that are added. The index and table of contents are updated with each supplement. CD-ROM purchasers receive a completely new disc every quarter and should dispose of their outdated discs. The material covered in the two versions is identical.

Subjects in this manual are organized by chapters and sections, and protocols are contained in units. Units generally describe a method and include one or more protocols with listings of materials, steps and annotations, recipes for unique reagents and solutions, and commentaries on the "hows" and "whys" of the method; there are also "overview" units containing theoretical discussions that lay the foundation for subsequent protocols.

BIOLOGICAL RESEARCH LIBRARY

Page numbering in the looseleaf version reflects the modular arrangement by unit; for example, page 2.3.5 refers to Chapter 2 (Computational Analysis), *UNIT 2.3* (Protein Secondary Structure Prediction), page 5 of that particular unit.

Many reagents and procedures are employed repeatedly throughout the manual. Instead of duplicating this information, cross-references among units are used extensively. Cross-referencing helps to ensure that lengthy and complex protocols are not overburdened with steps describing auxiliary procedures needed to prepare raw materials and analyze results.

Certain units that describe commonly used techniques and recipes (e.g., gel electrophoresis, ion-exchange chromatography) are cross-referenced in other units that describe their application. Thus, whenever it is necessary to isolate or identify a protein band in a protocol, the appropriate unit in Chapter 10—describing various procedures for gel electrophoresis—is cross-referenced (i.e., *UNIT 10.1*). For some widely used techniques (such as dialysis), readers are cross-referenced to *APPENDIX 3*.

Introductory and Explanatory Information

Because this publication is first and foremost a compilation of laboratory techniques in protein science, we have not provided extensive instructive material. We have, however, included explanatory information where required to help readers gain an intuitive grasp of the procedures. Chapter 1 provides an overview of strategies for protein purification and characterization, to help the reader plan for all aspects of an experimental study. Some subsequent chapters begin with special overview units that describe the state of the art of the topic matter and provide a context for the procedures that follow. Chapter and unit introductions describe how the protocols that follow connect to one another, and annotations to the actual protocol steps describe what is happening as a procedure is carried out. Finally, the Commentary that closes each protocol unit describes background information regarding the historical and theoretical development of the method, as well as alternative approaches, critical parameters, troubleshooting guidelines, anticipated results, and time considerations. All units contain cited references and many indicate key references to inform users of particularly useful background reading, original descriptions, or applications of a technique.

Protocols

Many units in the manual contain groups of protocols, each presented with a series of steps. The *basic* protocol is presented first in each unit and is generally the recommended or most univerally applicable approach. *Alternate* protocols are provided where different equipment or reagents can be employed to achieve similar ends, where the starting material requires a variation in approach, or where requirements for the end product differ from those in the basic protocol. *Support* protocols describe additional steps that are required to perform the basic or alternate protocols; these steps are separated from the core protocol because they might be applicable to other uses in the manual, or because they are performed in a time frame separate from the basic protocol steps.

Reagents and Solutions

Reagents required for a protocol are itemized in the materials list before the procedure begins. Many are common stock solutions, others are commonly used buffers or media, while others are solutions unique to a particular protocol. Recipes for the latter solutions are provided in each unit, following the protocols (and before the commentary) under the heading Reagents and Solutions. It is important to note that the *names* of some of these special solutions might be similar from unit to unit (e.g., SDS sample buffer) while the

BCU IAS CENTRAL UNIVERSITY LIBRARY

recipes differ; thus, make certain that reagents are prepared from the proper recipes. On the other hand, recipes for commonly used stock solutions and buffers are provided once in *APPENDIX 2E*. These universal recipes are cross-referenced parenthetically in the materials lists rather than repeated with every usage.

Commercial Suppliers

Throughout the manual, we have recommended commercial suppliers of chemicals, biological materials, and equipment. In some cases, the noted brand has been found to be of superior quality or it is the only suitable product available in the marketplace. In other cases, the experience of the author of that protocol is limited to that brand. In the latter situation, recommendations are offered as an aid to the novice protein science experimenter in obtaining the tools of the trade. Experienced investigators are therefore encouraged to experiment with substituting their own favorite brands.

Addresses, phone numbers, and facsimile numbers of all suppliers mentioned in this manual are provided in the *SUPPLIERS APPENDIX*.

Safety Considerations

Anyone carrying out these protocols may encounter the following hazardous or potentially hazardous materials: (1) radioactive substances, (2) toxic chemicals and carcinogenic or teratogenic reagents, and (3) pathogenic and infectious biological agents. Readers are referred to *APPENDIX 2A* and *APPENDIX 2B* for guidelines regarding use, storage, and disposal of these materials. Although cautionary statements are included in the appropriate units with cross-references to this appendix, we emphasize that users must proceed with the prudence and precaution associated with good laboratory practice, and that all materials must be used in strict accordance with local and national regulations.

Reader Response

Most of the protocols included in this manual are used routinely in our own laboratories. These protocols work for us; to make them work for you we have annotated critical steps and included critical parameters and troubleshooting guides in the commentaries to most units. However, the successful evolution of this manual depends upon readers' observations and suggestions. Consequently, a self-mailing reader-response survey can be found at the back of the manual (and is included with each supplement); we encourage readers to send in their comments.

ACKNOWLEDGMENTS

This manual is the product of dedicated efforts by many of our scientific colleagues who are acknowledged in each unit and by the hard work by the Current Protocols editorial staff at John Wiley and Sons. The publisher's commitment and continuing support for a protein science manual, particularly through the efforts of Brian Crawford and Paul Majchrzyk, was essential for realizing this ambitious project. We are extremely grateful for the critical contributions by Virginia Chanda (Series Editor) who kept the editors and the contributors on track and played a key role in bringing the entire project to completion. Other skilled members of the Current Protocols staff who contributed to the project include Janet Blair, Hazel Chan, Elizabeth Konkle, Alice Ro, and Kathy Wisch. The extensive copyediting required to produce an accurate protocols manual was ably handled by Rebecca Barr, Karen Hopkin, Arline Keithe, Kathy Morgan, Connie Parks, and Allen Ranz, and electronic illustrations were prepared by Gae Xavier. Finally, we would like to thank two people who played important roles in initiating this project. Sarah Greene

BCU INSTRUMENTAL UNIVERSITY LIBRARY

initially conceived this project and had a critical role in developing it. John A. Smith made important contributions during the early planning phases of the project.

Helpful advice and criticisms of the project during early planning stages were provided by Fred Ausubel, Charles S. Craik, Bruce A. Cummingham, Mark Hermodson, Tony E. Hugli, Robert Kingston, Albert Light, Paul Matsudaira, David Moore, George Rose, and Kevin Struhl. Mark Hermodson read and critiqued the entire manual and individual chapters were thoughtfully reviewed by John Freed and John Kay. Finally, we are especially grateful to our many colleagues, who contributed material to this manual, for sharing their procedures and experiences.

RECOMMENDED BACKGROUND READING

Branden, C. and Tooze, J. 1991. Introduction to Protein Structure. Garland Publishing, New York.

Easy-to-read overview of basic structural principles of proteins with extensive illustrations.

Jagow, G. and Schagger, H. 1994. A Practical Guide to Membrane Protein Purification. Academic Press, San Diego.

Deals with specific problems encountered when purifying membrane-associated proteins.

Kyte, J. 1994. Structure in Protein Chemistry. Garland Publishing, New York.

Comprehensive overview of structural principles of proteins with emphasis on physical chemistry approaches.

Scopes, R.K. 1994. Protein Purification: Principles and Practice. Springer-Verlag, New York.

In-depth description of most conventional protein purification methods.

Zubay, G.L., Parson, W.W., and Vance. D.E. 1995. Principles of Biochemistry. William C. Brown Publishers, Dubuque, Iowa.

A current biochemistry textbook whose protein-related chapters provide a comprehensive background for readers with no formal training in biochemistry.

Overview of Protein Purification and Characterization

AIMS AND OBJECTIVES

Protein purification has an over 200-year history: the first attempts at isolating substances from plants having similar properties to "egg albumen," or egg white, were reported in 1789 by Fourcroy. Many proteins from plants were purified in the nineteenth century, though most would not be considered pure by modern standards. A century later, ovalbumin was the first crystalline protein obtained (by Hofmeister in 1889). The year 1989 may not go down in history as a milestone in protein chemistry, but since then there has been a resurgence of interest in proteins after more than a decade of gene excitement.

The aims of protein purification, up until the 1940s, were simply academic. To then, even the basic facts of protein structure were not fully appreciated, and pure proteins were needed just to study structure and test the rival theories of the pre-DNA days. During the Second World War, an acute need for blood proteins led to development of the Cohn fractionation procedure for purification of albumin and other proteins from serum (Cohn et al., 1946). This was the inception of large-scale protein purifications for commercial purposes; Cohn fractionation continues to be used to this day.

As more proteins, and particularly enzymes, were purified and crystallized, they started to be used increasingly in diagnostic assays and enzymatic analyses, as well as in the large-scale food, tanning, and detergent industries. Many enzymes used in industry are not in fact very pure, but as long as they do the job, that is sufficient. "Process" enzymes such as α-amylase, proteases, and lipases are pro-duced in ton quantities, mainly as secretion products in bacterial cultures, and may undergo only limited purification processes to mini-mize costs. At the other extreme, enzyme products for research and analysis require a high degree of purification to ensure that contaminating activities do not interfere with the intended use. Anyone familiar with molecular biology enzymes will appreciate how minute levels of contamination of DNase or RNase can completely destroy carefully planned experiments.

The 1960s and 1970s could be described as the peak years for protein and enzyme research, and most of the methods used in protein purification were established by then, at least in their principles. More recent developments have been mainly in instrumentation designed to optimize the application of each methodology. Developments in instrumentation have been stimulated by the rapid progress in molecular biology, because gene isolation has often been preceded by isolation of the gene product. Because such products can now be characterized sufficiently (i.e., partially sequenced) using minute amounts of protein, the need for large-scale or even moderate-scale procedures has decreased. Hence there has been an explosive development of modern equipment designed specifically for dealing with amounts of protein in the milligram to microgram range. On the other hand, structural studies using X-ray crystallography and nuclear magnetic resonance (NMR) require hundreds of milligrams of pure protein, so larger-scale equipment and procedures are still needed in the research laboratory.

The nature of the proteins studied has also changed substantially. Whereas enzymes were once the most favored subjects, they have now been superceded by nonenzymatic proteins such as growth factors, hormone receptors, viral antigens, and membrane transporters. Many of these occur in minute amounts in the natural source, and their purification can be a major task. Heroic efforts in the past have used kilogram quantities of rather unpleasant starting materials, such as human organs, and ended up with a few micrograms of pure product. It is now more usual, however, to take the genetic approach: clone the gene before the protein has been isolated or even properly identified, then express it in a suitable host cell culture or organism. The expression level may be orders of magnitude higher than in the original source, which will make purification a relatively simple task. It can be useful to know beforehand some physical properties of the protein, to facilitate the development of a suitable purification protocol from the recombinant source. On the other hand, there are now several ways of preparing fusion proteins, which can be purified by affinity techniques without any knowledge of the properties of the target protein. Moreover, there are ways of modifying the expressed product to simplify purification further.

LIBRARY

Thus the approach to protein purification must first take into account the reason it is being done, as the methods will vary greatly with different requirements. At one extreme is the one-of-a-kind purification, in a well-financed and equipped laboratory, that is carried out to obtain a small amount of product for sequencing so that gene isolation can proceed. In this case, expense of equipment and reagents may be no problem, and a very low overall recovery of product can be acceptable, provided it is pure enough. At the other extreme are the requirements of commercial production of a protein in large amounts on a continuing basis, where high recovery and economy of processing are the chief parameters to be considered. There are many intermediate situations as well.

Many publications in the area of protein research are entitled "Purification and characterization of...," and describe a purification procedure in sufficient detail that it can be reproduced in another laboratory. The characterization section may include structural, functional, and genetic information, and carrying out such studies is likely to require at least milligram quantities of pure protein. Ideally the purification should involve a small number of steps, with good recovery at each step. If the recovery is poor (<50% at any step), however, there should be some indication of what happened to the missing activity. Has it been discarded in the other fractions for the sake of purity, or does it represent a true loss of activity? If the latter, then the end-product may be less than fully active despite apparent homogeneity indicated by standard analysis. The choice between recovery and purification at each step can be problematical; taking a narrow cut of a chromatographic peak may provide a very pure fraction, at the expense of losing a good deal of less pure active component on either side. In making such decisions, the objective of the exercise must be kept in mind: if yield is not important, then the choice of poor yield for the sake of purity may be logical.

By far the most important requirement of a publication is reproducibility of the method reported. It is not sufficient to have carried out the process only once if it is expected that other investigators will want to repeat it. There are always factors that influence the process that may be overlooked at first, and which if varied slightly can have a major effect on the purification procedure. The reported process should always be repeated exactly as described before submitting the manuscript for publication. There is one exception, namely, the case where purification was conducted simply to obtain enough protein for sequencing and gene isolation; if that was achieved, there should be no need to provide instructions for repetition.

SOURCES OF MATERIAL FOR PROTEIN PURIFICATION

For many people embarking on a protein purification project, there is no choice of material. They are studying a particular biological tissue or organism, and the objective is to purify a protein from that source. However, there may be approaches that can make the project simpler. If, for instance, the source is difficult to obtain in large amounts, it may be best to carry out at least preliminary trials on a source species more readily obtained. The most obvious and relevant example is when the species being studied is *Homo sapiens*, and tissue samples are not readily available for practical or ethical reasons, or both. In this case, it is usual to go to where mammalian tissue is readily available (i.e., an abattoir) and work with bovine, ovine, or porcine sources. Alternatively, if quantity of tissue is not a problem, the humble laboratory rat may suffice. Once a protocol for purifying the protein from substitute sources has been worked out, it will be much easier to develop one using human material—the identical procedure may work satisfactorily. Proteins differ to a fairly small extent between species that have diverged within about 100 million years, a time frame that groups together most higher mammals. Thus the behavior of proteins derived from different animals with respect to the various fractionation procedures is likely to be similar, and a protocol worked out for pig tissues is likely to need only minor adjustments for application to human tissues.

A second example is where the interest is mainly on the function of a protein, especially an enzyme, for which functions and actions have generally been strongly conserved through evolution. In that case, a preliminary screening of potential sources, or, better still, the literature, should come up with a raw material that is best suited to the investigator's purposes. Considerations should include the following: (1) What functions are required of the end product? For instance, an enzyme having a low K_m may be needed, so selecting the source with the highest activity may not suffice. (2) How convenient is it to grow or obtain the raw material, and are there problems concerning pathogenicity or extractability? (3) Does the quantity of the protein vary with growth conditions or age, and does it deteriorate in situ

if left too long? Obviously one requires a source that reliably produces the highest amount of the desired protein per unit volume to maximize the chances of developing a good purification procedure. (4) What storage conditions are required for the raw material? It is important to consider that fresh raw material may not be immediately available whenever a purification is attempted.

The above considerations are relevant to the traditional situation for commencing a protein purification project. It is becoming increasingly common, however, for proteins to be purified as recombinant products using techniques in which the gene is expressed in a host organism or in cultured cells. This of course requires the gene encoding the protein of interest to be available. Until the mid-1980s, such material was usually obtained by hybridization of an oligonucleotide synthesized according to amino acid sequence information. This required the protein to have been purified first, so the initial task of protein purification still needed to be done at least once. More recently, genetic techniques have permitted the isolation of many genes encoding known proteins, even though the proteins may never have been studied directly. Moreover, with the expansion of the Human Genome Project and related DNA sequencing efforts, many genes for both known and unknown proteins will become available and will be able to be expressed in recombinant form without ever being purified from the host species. As a result some completely new considerations for protein purification come into play, including the possibility of modifying the gene structure not only to increase expression level and alter the protein product itself to enhance a desired function, but equally importantly to aid in purification. Recombinant proteins may be expressed in bacteria, yeasts, insect cells, and animal tissue cultures. Further details may be found in *UNIT 1.2*.

DETECTION AND ASSAY OF PROTEINS

During a protein purification procedure there are two measurements that need to be made, preferably for each fraction. Measurements both of the total protein and of the amount (usually bioactivity) of the desired protein must be made. Details of the most commonly used assay methods are given in Chapter 3. It is not possible to isolate a protein without a method of determining whether it is present; an assay, either quantitative or at least semi-quantitative, indicating which fraction contains the most of the desired protein is essential.

Assays may range from the quick-and-easy type (e.g., instantaneous spectrophotometric measurement of enzyme activity) to long and tedious bioassays that may take days to produce an answer. The latter situation is very difficult, because by the time one knows where the protein is, it may be "was," owing to degradation or inactivation. Moreover, this may not become clear until the next step has been completed and its products assayed. Any assay that is quick is therefore advantageous, even if it means a sacrifice of accuracy for speed.

Measurement of total protein is useful, as it indicates the degree of purification at each step. However, unless the next step critically depends on how much protein is present, total protein measurement is not extremely important: a small sample can be put aside and measured later, when the purification is complete. It is, however, very important to know how much protein is present in the final, presumed pure sample, as this will indicate the specific activity (if the protein has an activity), which can be compared with other preparations. The general object is to obtain as high a specific activity as possible (taking into account recovery considerations), which means retaining as much of the desired protein as possible while ending up with as little total protein as possible.

METHODS FOR SEPARATION AND PURIFICATION OF PROTEINS

The methods available for protein purification range from simple precipitation procedures used since the nineteenth century to sophisticated chromatographic and affinity techniques that are constantly undergoing development and improvement. Methods can be classified in several alternative ways—perhaps one of the best is based on the properties of the proteins that are being exploited. Thus the methods can be divided into four distinct but interrelated groups depending on protein characteristics: surface features, size and shape, net charge, and bioproperties.

Methods Based on Surface Features of Proteins

Surface features include charge distribution and accessibility, surface distribution of hydrophobic amino acid side chains, and, to a lesser extent, net charge at a given pH (see discussion of net charge). Methods exploiting surface fea-

BOULDER COLORADO STATE LIBRARY

tures mainly depend on solubility properties. Differences in solubility result in precipitation by various manipulations of the solvent in which the proteins are solubilized. Methods for obtaining an extract containing the desired protein in soluble form are given in Chapter 4. The solvent, nearly always water containing a low concentration of buffer salts, can be treated to alter properties such as ionic strength, dielectric constant, pH, temperature, and detergent content, any of which may selectively precipitate some of the proteins present. Conversely, proteins may be selectively solubilized from an insoluble state by manipulation of the solvent composition. The surface distribution of hydrophobic residues is an important determinant of solubility properties; it is also exploited in hydrophobic chromatography, both in the reversed-phase mode (*UNIT 11.6*) and in aqueous-phase hydrophobic-interaction chromatography (*UNIT 8.4*).

Also included in this group is the highly specific technique of immunoaffinity chromatography, in which an antibody directed against an epitope on the protein surface is used to pull out the desired protein from a mixture.

Methods Based on Whole Structure: Size and Shape

Although the size and shape of proteins can have some influence on solubility properties, the chief method of exploiting these properties is gel-filtration chromatography (*UNIT 8.3*). In addition, preparative gel electrophoresis makes use of differences in molecular size. Proteins range in size from the smallest classified as proteins rather than polypeptides, around 5000 Da, up to macromolecular complexes of many million daltons. Many proteins in the bioactive state are oligomers of more than one polypeptide (see *UNIT 1.2*), and these can be dissociated, though normally with loss of overall structure. Thus many proteins have two "sizes": that of the native state, and that (or those) of the polypeptides in the denatured and dissociated state. Gel-filtration procedures normally deal only with native proteins, whereas electrophoretic procedures commonly involve separation of dissociated and denatured polypeptides.

Methods Based on Net Charge

The two techniques that exploit the overall charge of proteins are ion-exchange chromatography (by far the most important) and electrophoresis (Chapter 10). Ion exchangers bind charged molecules, and there are essentially only two types of ion exchangers, anion and cation. The net charge of a protein depends on the pH—positive at very low pH, negative at high pH, and zero at some specific point in between, termed the isoelectric point (pI). It should be stressed that at the pI a protein has a great many charges; it just happens that at this pH the total negatives exactly equal the total positives. The most charged state (disregarding the charge sign) is in the pH range 6.0 to 9.0. This is the most stable pH range for most proteins, as it encompasses common physiological pH values. Ion exchangers consist of immobilized charged groups and attract oppositely charged proteins. They provide the mode of separation that has the highest resolution for native proteins. High-performance reversed-phase chromatography has equivalent or even better resolution, but it generally involves at least partial denaturation during adsorption and so is not recommended for sensitive proteins such as enzymes. Protein purification using ion-exchange chromatography has mainly employed positively charged anion exchangers, for the simple reason that the majority of proteins at neutral pH are negatively charged (i.e., have a low isoelectric point). Details of methodology are found in *UNIT 8.2*.

Methods Based on Bioproperties (Affinity)

A powerful method for separating the desired protein from others is to use a biospecific method in which the particular biological property of the protein is exploited. The affinity approach is limited to proteins that have a specific binding property, except that proteins are theoretically able to be purified by immunoaffinity chromatography (*UNIT 9.1*), which is the most specific of all affinity techniques. Most proteins of interest do have a specific ligand: enzymes have substrates and cofactors, and hormone-binding proteins and receptor molecules are designed to bind specifically and tightly to particular hormones and other factors. Immobilization of the ligand to which the protein binds (or of antibody to the protein) enables selective adsorption of the desired protein in the technique known as affinity chromatography (Chapter 9). There are also non-chromatographic modes of exploiting biospecific interactions.

CHARACTERIZATION OF THE PROTEIN PRODUCT

Once a pure protein is obtained, it may be employed for a specific purpose, such as enzymatic analysis (e.g., glucose oxidase and lac-

PGU IASRI LIBRARY

tate dehydrogenase), or as a therapeutic agent (e.g., insulin and growth hormone). However, it is normal, when a protein has been isolated for the first time, to characterize it in terms of structure and function. Several features are generally expected in characterization of a new protein. These include molecular weight, or at least the size of the subunit(s), determined by SDS-polyacrylamide gel electrophoresis (Chapter 10) and/or gel filtration (*UNIT 8.3*). Spectral properties such as the UV spectrum (Trp and Tyr content), circular dichroism (CD) spectrum (secondary structure), and special characteristics of proteins with prosthetic groups (e.g., quantitation and spectra) may be presented. The quantity and nature of carbohydrates on glycoproteins should be determined (Chapter 12). Also, if the gene has not already been reported, some amino-terminal sequence analysis should be given, if at all possible, along with the results of a database search for similar sequences (*UNIT2.1*). Functional proteins should be demonstrated to have the appropriate function, and for enzymes detailed kinetic characterization is appropriate. Ultimately the full three-dimensional structure of the protein may be determined, which will require crystals: any successful crystallization attempts should be reported.

THE PROTEIN PURIFICATION LABORATORY

The requirements for a protein purification laboratory cannot be exactly formulated because they depend greatly on the types and amounts of proteins being isolated. To cover all eventualities, it would be necessary to have one set of equipment to deal with submicrogram quantities and another set to deal with multigram quantities—a range of around 10^8! One laboratory dedicated to protein purification may not need small-scale equipment if, for example, it works with plasma proteins that are always available in large quantities. Another may have all the latest in high-performance equipment but not be able (nor need) to handle quantities of protein in excess of a few milligrams.

If it is assumed that neither extreme in quantity is to be attempted, and that the laboratory is handling a variety of protein types and sources, then certain basic pieces of equipment are needed. Obtaining the starting material and making an extract of it require homogenization equipment and centrifuges to remove insoluble residues. Preliminary fractionation, when starting with a crude extract of tissue or cells, requires equipment and materials that will not become clogged by particulates. Adsorbents and similar materials used at the first step should be relatively inexpensive so that when performance falls off after a few uses, owing to intransigent impurity buildup, they can be discarded. It is also relevant that a larger amount is handled at the initial step than later steps; therefore, reagent expense can be an important consideration. After the first one or two steps, the sample should be sufficiently clean and clear to enable use of high-performance equipment.

High-performance liquid chromatography, or HPLC, is a term with a variety of meanings. To some it refers exclusively to reversed-phase chromatography; to others it includes all sorts of chromatography provided that the equipment is fully automated and high-performance adsorbents are used. A high-performance system designed specifically for proteins—introduced by Pharmacia Biotech (see *SUPPLIERS APPENDIX*) called Fast Protein Liquid Chromatography, or FPLC—uses standard protein chromatographies such as ion exchange, hydrophobic interaction, and gel filtration. Scaleup is possible with larger equipment based on the FPLC design, so that laboratory development can be quickly translated to large-scale production. FPLC is designed to separate proteins in their native active configuration, whereas reversed-phase HPLC often causes at least transient denaturation during adsorption and elution. Reversed-phase HPLC has a high resolving power, but it is best suited to peptides and proteins smaller than ~30 kDa. Chromatography run with older-style low-pressure adsorbents is sometimes referred to as "low-performance" or "open-column" chromatography; neither of those descriptions is necessarily accurate. Simple fraction collector and monitoring equipment is needed. This equipment will be used for larger-scale operations (tens of milligrams of protein and upward), probably at an earlier stage in the protocol than with HPLC.

Various columns, both prepacked with proprietary adsorbents and empty for self-packing, will be needed, with the sizes and types depending on the scale of operations. Several anion-exchange columns (different sizes), one or two cation-exchange columns, and gel-filtration media are essential, along with a range of alternative adsorbents such as hydrophobic interaction materials, dyes, hydroxyapatite, and chromatofocusing and specialist affinity media.

MASS CENTRAL LIBRARY

Fully equipped protein purification laboratories should also have preparative electrophoresis and isoelectric focusing apparatuses for rare occasions when other techniques fail to give sufficient separation.

In addition to equipment used in the actual fractionation processes, a variety of other items are needed. In particular it should be possible to change buffers quickly and to concentrate protein solutions with ease. These operations require such things as dialysis membranes (*APPENDIX 3B*), ultrafiltration cells, and gel-exclusion columns of various sizes (*UNIT 8.3*).

Finally, equipment for assaying and analyzing the preparations is needed. Most such equipment is fairly standard in biochemical laboratories and includes spectrophotometers, scintillation counters, analytical gel and capillary electrophoresis apparatuses, immunoblotting materials, and immunochemical reagents. A listing of standard equipment is found in *APPENDIX 2D*.

Strategies for Protein Purification

CLASSIFICATION OF PROTEINS

As with most heterogeneous collections of things, proteins can be classified in several different ways, such as by function, by structure, or by physicochemical characteristics. Each protein species consists of identical molecules with exactly the same size, amino acid sequence, and three-dimensional shape. In this way a solution of a mixture of proteins differs from a solution of synthetic polymers or sheared DNA, both of which contain a complete spectrum of possible sizes centered around the average. The protein mixture has only discrete sizes of molecules corresponding to each type of protein present. Although we could classify proteins by size, it would be of limited use, as there is usually no obvious relationship between size and function.

A more useful structural classification takes into consideration shape and oligomeric structure (Table 1.2.1). In part, structure reflects biological location and origin. Simple, fairly rigid protein molecules occur in the extracellular environment, more complex and readily deactivated molecules are found intracellularly, and hydrophobic proteins are associated with membranes.

Classification by function is more relevant (Table 1.2.2). Proteins can be simply stores of amino acids, can be structural, or can have specific binding functions. The most "functional" proteins are enzymes, which have both binding and catalytic roles. In part, this reflects the degree to which the detailed structure is a requirement for the protein's function, which in turn relates to conservation of structure through evolution. But as with every attempt at classification, there are going to be examples that do not fit the pattern well. Most proteins of interest to the pharmaceutical industry belong to the general class of binding proteins, for instance, hormones [e.g., insulin and bovine somatostatin (BST)], viral antigens (e.g., hepatitis B antigen), growth factors [e.g., interferons, interleukins and colony-stimulating factors (CSFs)], and antibodies.

STRATEGIES FOR PROTEIN PURIFICATION

Soluble Extracellular Proteins

The source of soluble extracellular proteins is the extracellular medium, whether it be an animal source such as blood or spinal fluid, or a culture medium in which bacterial, fungal, animal, or plant cultures have been grown. Generally these do not contain a large number of different proteins (blood is an exception), and the desired protein may be a major component, especially if produced as the result of recombinant expression. Nonetheless, the protein in the starting material may be quite dilute,

Table 1.2.1 Classification of Proteins by Structural Characteristics

Structural characteristic	Examples	Comments
Monomeric	Lysozyme, growth hormone	Usually extracellular; often have disulfide bonds
Oligomeric		
Identical subunits	Glyceraldehyde-3-phosphate dehydrogenase, catalase, alcohol dehydrogenase, hexokinase	Mostly intracellular enzymes; rarely have disulfide bonds
Mixed subunits	Aspartate carbamoyltransferase, pertussis toxin	Allosteric enzymes; different subunits have separate functions
Membrane-bound		
Peripheral	Mitochondrial ATPase, alkaline phosphatase	Readily solubilized by detergents
Integral	Porins, cytochromes P_{450}, insulin receptor	Require lipid for stability
Conjugated	Glycoproteins, lipoproteins, nucleoproteins	Many extracellular proteins contain carbohydrate

Table 1.2.2 Classification of Proteins by Function

Function	Examples
Amino acid storage	Seed proteins (e.g., gluten), milk proteins (e.g., casein)
Structural	
Inert	Collagen, keratin
With activity	Actin, myosin, tubulin
Binding	
Soluble	Albumin, hemoglobin, hormones
Insoluble	Surface receptors (e.g., insulin receptor), antigens (e.g., viral coat proteins)
With activity	Enzymes, membrane transporters (e.g., amino acid uptake systems, ion pumps)

and a large volume may therefore need to be processed. The starting fluid may also contain many compounds other than proteins, whose behavior must be taken into account. The first stage should aim mainly to reduce the volume and get rid of as much nonprotein material as possible; some protein-protein separation is also useful, but not essential. No general rules can be given, but a batch adsorption method using an inexpensive material such as hydroxyapatite, ion-exchange resin, immobilized metal affinity chromatography (IMAC) medium, or affinity adsorbent is best, if feasible. Following the first step, the sample should be in a form that is amenable to standard purification processes such as precipitation and column chromatography (Chapter 8).

Intracellular (Cytoplasmic) Proteins

To obtain soluble intracellular proteins (which are mainly enzymes), cells must be broken open or lysed to release their soluble contents. The ease with which cell disruption can be accomplished varies considerably; animal cells are readily broken, as are many bacteria, but plants and fungi have tough cell walls. Methods for obtaining cell extracts are given in Chapter 4. The macromolecular soluble contents of cells are mainly proteins, with nucleic acids as a minor but significant component. Bacterial extracts may be viscous unless DNase is added to break down the long DNA molecules. Although chromatographic procedures can be applied to crude extracts, valuable high-performance materials should not be employed in the first step, as there are always compounds, including unstable proteins, that may bind to them and be difficult to remove.

Membrane-Associated Proteins

There are two approaches to isolating a membrane-associated protein. In one method, the relevant membrane fraction can first be prepared and then used to isolate the protein. Alternatively, whole tissue can be subjected to an extraction that solubilizes the membranes and releases the cytoplasmic contents as well. The former is much better in that purification is accomplished by isolating the membranes: the specific activity of the solubilized membrane fraction will be much higher than in the second method. However, the process of purifying the membrane fraction may lead to substantial losses, and it may be difficult to scale up. If total recovery of the protein is more important than purity, a whole-tissue extract is likely to be more appropriate. Although this means that a greater degree of purification is needed, the fact that membrane proteins have, by definition, properties somewhat different from those of cytoplasmic proteins permits some very effective purification steps (e.g., hydrophobic chromatography or fractional solubility separation).

Peripheral membrane proteins are only loosely attached and may be released by gentle conditions such as high pH, EDTA, or low (nonionic) detergent concentrations. Once in solution, some peripheral proteins no longer require the presence of detergent to maintain their solubility. Integral membrane proteins are much more difficult—they require high concentrations of detergent for solubilization (i.e., complete solubilization of the membrane is needed to release them) and generally are neither soluble nor stable in the absence of detergent. It is sometimes necessary to maintain

BCU IAS CENTRAL UNIVERSITY LIBRARY

natural phospholipids in association with the proteins in order to maintain activity. Even though the final objective may not require activity (e.g., amino acid sequencing), there is a need for some sort of assay during the purification process to determine where the protein is. If a particular band on a gel is known to be the desired protein, then no other assay is needed and loss of bioactivity can be allowed.

Purification processes may be affected by the presence of detergents. The problem of association with detergent micelles makes purifying integral membrane proteins difficult; the close association of the different proteins originating from membranes often results in very poor separation in conventional fractionation procedures.

Insoluble Proteins

Natural proteins that are insoluble in normal solvents are generally structural proteins, which are sometimes cross-linked by post-translational modification. The first stage of purification is obvious—it involves extracting and washing away all proteins that are soluble, leaving the residue containing the desired material. Further purification in a native state, however, may be impossible; extracting away other proteins using more vigorous solvents or attempting to solubilize the target protein may destroy the natural structure. Cross-linked proteins such as elastin or aged collagen cannot be dissolved without breaking the cross-links, and the individual proteins may even be cross-linked together.

Insoluble Recombinant Proteins (Inclusion Bodies)

A major new class of insoluble proteins are recombinant proteins expressed (usually in *Escherichia coli*) as inclusion bodies. These are dense aggregates found inside cells that consist mainly of a desired recombinant product, but in a nonnative state. Inclusion bodies may form for a variety of reasons, such as insolubility of the product at the concentrations being produced, inability to fold correctly in the bacterial environment, or inability to form correct, or any, disulfide bonds in the reducing intracellular environment. Their purification is simple, since the inclusion bodies can be separated by differential centrifugation from other cellular constituents, giving almost pure product; the problem is that the protein is not in a native state, and is insoluble. Some methods for obtaining an active product from inclusion bodies are described in *UNIT 6.3*.

Soluble Recombinant Proteins

Recombinant proteins that are not expressed in inclusion bodies either will be soluble inside the cell or, if using an excretion vector, will be extracellular (or, if *E. coli* is the host, possibly periplasmic). They can be purified by conventional means. In some systems, expression is so good that the desired product is the major protein present and its purification is relatively simple. In systems where the expression level is low, the purification process can be tedious, though easier, it is hoped, than isolation from the natural source. It should be remembered that a procedure developed for isolating a protein from natural sources may not work successfully with the recombinant product, because the nature of the other proteins present influences many fractionation procedures.

Because of the difficulties often experienced in purifying recombinant proteins, a variety of vector systems (see *UNIT 6.1* and Sassenfeld, 1990, for some examples) have been developed in which the expressed product is a fusion protein containing an N-terminal polypeptide that simplifies purification. Such "tags" can be subsequently removed using a specific protease. A further advantage is that the expression level is dictated mainly by the transcription and translation signals for the fusion portion of the protein, which are optimized. Tags used include proteins and polypeptides for which there is a specific antibody, binding proteins that will interact with columns containing a specific ligand, polyhistidine tags with affinity to immobilized metal columns, sequences that result in biotinylation by the host and enable purification on an avidin column, and sequences that confer insolubility under specified conditions (*UNIT 6.1 & UNIT 6.5*).

Unstable proteins may be modified by the molecular biological technique of site-directed mutagenesis to remove the site of instability—for instance, an oxidizable cysteine. Such techniques are appropriate for commercial production of proteins, but may of course alter natural functioning parameters. Increased thermostability can be one modification, although it is not easy to predict mutations that will improve that parameter. Thermostable proteins originating from thermophilic bacteria do not need structural modification and, if expressed in large amounts, can be purified satisfactorily in one step by simply heat-treating the extract at 70°C for 30 min, which denatures virtually all the host proteins (e.g., see Oka et al., 1989).

The host bacteria used for production of

UNIT 1.2
LIBRARY

recombinant proteins are usually *Escherichia coli*, or *Bacillus subtilis*; they may express proteins at 1% to over 50% of the cellular protein, depending on such variables as the source, promoter structure, and vector type. Generally the proteins are expressed intracellularly, but leader sequences for excretion may be included. In the latter case, the protein is generally excreted into the periplasmic space, which limits the amount that can be produced. Excretion from gram-positive species such as *B. subtilis* sends the product into the culture medium, with little feedback limitation on total expression level.

Protein Purification Flow Charts

Protein purification flow charts are presented to give a broad outline of the methods used for different types of proteins. They cannot give any detail, as the process appropriate for each protein will have its own variations at each stage. In most cases, the first stage is to obtain a solution containing the desired protein, after which it can be dealt with by the many separation techniques described in the following chapters. In some cases the insolubility of the desired protein can be exploited by removing soluble fractions. Purification procedures are commonly divided into three stages: (a) the primary steps, which deal with crude mixtures of proteins and other molecules present in the raw material; (b) the secondary processing, which generates a product near to homogeneity; and (c) the polishing steps, which remove minor contaminants, a process that is especially important for therapeutic proteins.

SOLUBLE RECOMBINANT PROTEINS

Proteins expressed in a recombinant manner may be (1) soluble in the cytoplasm, (2) insoluble as inclusion bodies (see section on Insoluble Recombinant Proteins), (3) excreted from the cells into the culture medium, (4) excreted into the periplasmic space (e.g., in gram-negative bacteria), or (5) associated with organelles or membrane fractions. In addition they may be expressed (6) as the normal, mature, naturally occurring protein, (7) containing a natural leader peptide that would normally be processed, (8) as a fusion protein with a peptide that is not natural to the protein, or (9) lacking glycosylation or other post-translational modification, or incorrectly modified. Possibilities (1) to (5) affect the method of extraction used to obtain the starting material for purification. Cases (6) to (9) can affect the methods used for purification.

The scheme for purifying soluble recombinant proteins is outlined in Figure 1.3.1. The first stage is to obtain a clarified solution containing the desired protein, with as little in the way of unwanted proteins as possible. For soluble cytoplasmic proteins, case (1), it is not normally possible to exclude any significant amount of unwanted soluble proteins, but in cases (2) to (5) the compartmentalization away from the cytoplasm allows such separation in the initial stage.

It may be necessary to carry out a concentration step before proceeding, especially if the protein has been excreted into the culture medium. Normally ultrafiltration is used, although other techniques are possible, especially if the extract contains particulates that block ultrafiltration membranes.

Recombinant expression in the cytoplasm of bacteria, followed by extraction via total cell disruption, results in large amounts of nucleic acids being solubilized with the protein. A number of treatments to remove nucleic acids are possible. Streptomycin is used to precipitate ribosomal material, and cationic polymers such as protamine (a basic protein) and polyethylenimine will form insoluble complexes (at low ionic strength) with nucleic acids. In addition, viscosity caused by DNA can be reduced by adding small amounts of DNase.

INSOLUBLE RECOMBINANT PROTEINS

It has been found that many proteins expressed in bacteria (mainly in *Escherichia coli*) do not fold correctly, and as a result aggregation occurs, leading to large insoluble inclusion bodies within the cytoplasm of the cells (see Chapter 6). Although this creates major difficulties in obtaining satisfactory amounts of active native product, it greatly simplifies the initial stage of purification.

The purification scheme for recombinant insoluble proteins is outlined in Figure 1.3.2. After cell disruption, inclusion bodies can be obtained in a fairly pure state by differential centrifugation. They must now be solubilized, however, and the active protein generated by encouraging correct folding. Solubilization is usually accomplished with guanidine hydrochloride and/or urea, and thiols such as 2-mercaptoethanol or glutathione are included to disrupt any disulfides that have formed and prevent more from forming. Folding the protein correctly may require a variety of additions to the solution, as well as slow removal of the denaturant. The latter can be carried out by simple dilution or by dialysis. Folding occurs best at low protein concentrations, so dilution may be adequate. If the native protein does contain disulfides, then it is important to create redox conditions such that some (but not excessive) oxidation of thiols can occur. A combination of oxidized and reduced glutathione is commonly used. In addition, the action of the enzyme protein disulfide isomerase, which can

for tagged fusion protein, use affinity column chromatography and polishing steps
purified protein

Figure 1.3.1 Purification scheme for soluble recombinant proteins, which may be excreted or located in the periplasm, in the membrane fraction, or most commonly the cytoplasm. The first step is to obtain an extract containing the desired protein in soluble form. After this, conventional purification steps may be carried out, or affinity purification of tagged fused proteins can be performed.

make and unmake disulfides by exchange reactions, has been found to be beneficial in many cases. If the native protein is of intracellular origin, it probably will not contain disulfides; it will, however, contain cysteines, so a full reducing potential should be maintained. Specific methodology is discussed in *UNIT 6.5*.

Not all proteins can fold unassisted by other cellular components. Chaperonins are proteins whose role is to refold denatured proteins such as those that form during heat shock (Zeilstra-Ryalls et al., 1991). The most studied, and just becoming commercially available as of 1995, are the *E. coli* chaperonins GroEL and GroES, both of which are needed, together with ATP, to renature many proteins. Proline residues can adopt two isomeric conformations in proteins, and the wrong conformation is switched to the correct one by the enzyme prolyl isomerase, aiding the process of protein folding. At present these are not large-scale prospects, both because of the cost of the chap-

RCU IASRI / CENTRAL UNIVERSITY LIBRARY

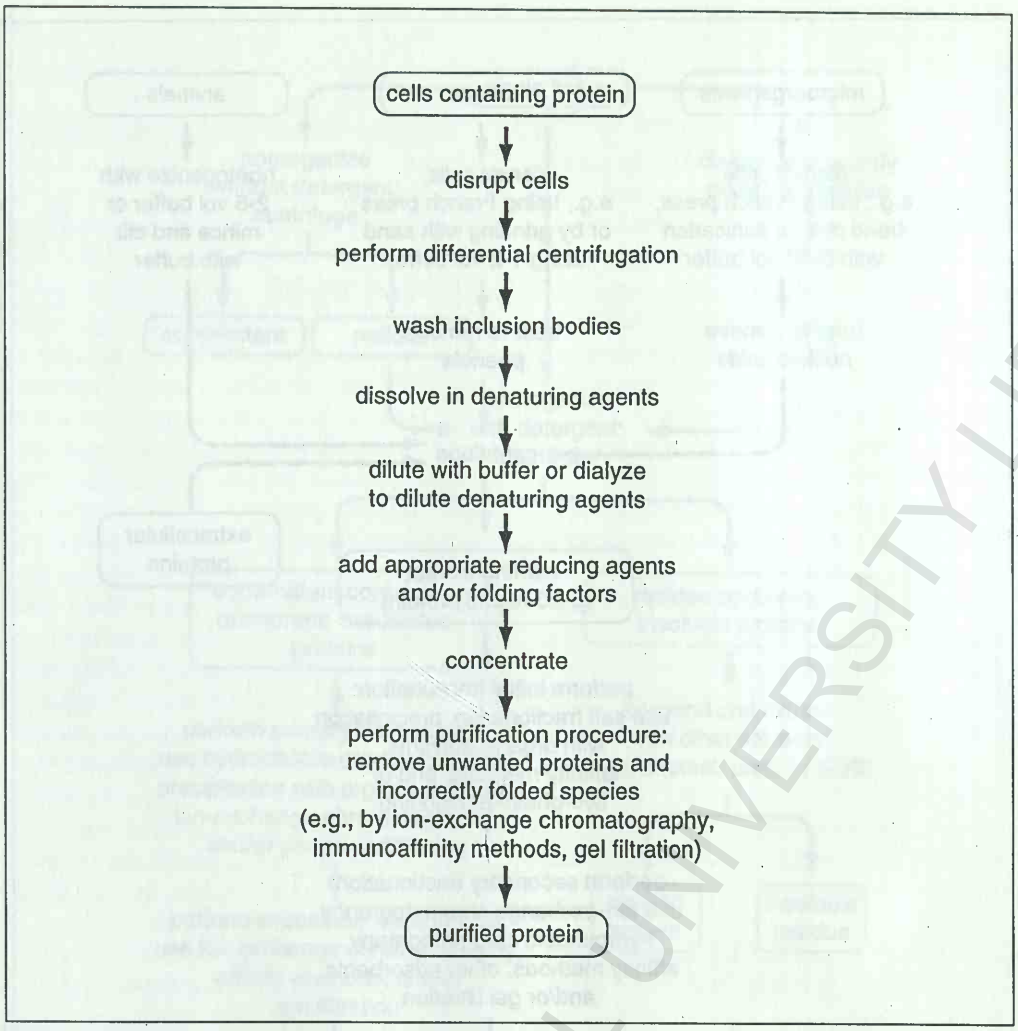

Figure 1.3.2 Purification scheme for insoluble recombinant proteins that are produced as inclusion bodies in the cytoplasm of host cells. The cells must be broken open, and then the insoluble inclusion bodies are separated by differential centrifugation. Solubilization is achieved by the use of denaturing solvents, and renaturation of the dissolved protein occurs on removal of the denaturant. Further polishing steps will be needed to remove small amounts of contaminating proteins as well as incorrectly folded species. Additional information can be found in *UNIT 6.3-6.5.*

eronins and because the agents operate best in vitro at very low protein concentrations.

Once the proteins are folded, the purification process consists of removing small amounts of still incorrectly folded protein plus any other host proteins that were trapped with the original inclusion bodies. The former may be difficult, since incorrectly folded species have a size and charge similar to those of the correct product. However, subtle differences arising from the folded conformation can be exploited by chromatographic techniques. In ideal cases immunoaffinity techniques using antibodies specific for either the incorrectly folded form or the correct one can be used to resolve the mixture.

SOLUBLE NONRECOMBINANT PROTEINS

There are so many sources of soluble proteins that it is not possible to give a complete overview of methods used to obtain starting extracts from which a desired protein can be isolated. The sources can be classified as either microorganisms, plants, or animals, as shown in Figure 1.3.3, but these in turn should be subdivided according to how the starting extract is obtained. In particular there is a distinction between extracellular and intracellular proteins. With the latter it is necessary to disrupt the cells and release the proteins, whereas with the former, if the extracellular fluid can be obtained directly, there need be no contamination with intracellular proteins. Extracellular

microorganisms
plants
animals
disrupt cells, e.g., using French press, bead mill, or sonication with 5-10 vol buffer
disrupt cells, e.g., using French press or by grinding with sand using 1-2 vol buffer
homogenize with 2-5 vol buffer or mince and stir with buffer
treat to remove nucleic acids
treat to remove phenols
centrifuge
extracellular proteins
starting extract (5-20 mg/ml protein)
perform initial fractionation: use salt fractionation, precipitation with organic solvents, affinity methods, and/or two-phase partitioning
perform secondary fractionation: use ion-exchange chromatography, hydrophobic chromatography, affinity methods, other adsorbents, and/or gel filtration
perform polishing step: use HPLC–reversed phase, HPLC–ion exchange, or isoelectric focusing
purified protein

Figure 1.3.3 Purification scheme for soluble proteins present in their natural host cells. Cells must be disrupted to release the proteins, usually in the presence of 2 to 10 ml of a suitable buffer per gram weight. After removal of insoluble material, the process will generally require several steps, using various standard fractionation procedures in a suitable order. For production of highly pure protein, a final polishing step may be required to remove final trace contaminants. Additional information can be found in *UNIT 6.2*.

sources include microorganism culture medium, plant and animal tissue culture medium, venoms, milk, blood, and cerebrospinal fluids. Soluble proteins may also occur within organelles such as mitochondria; these may be best obtained by first isolating the organelle, then disrupting it to release the contents.

The starting extract normally contains between 5 and 20 mg protein per milliliter, though lesser concentrations can be dealt with, especially if working on a small scale. It may be necessary to include a concentration step before starting the purification process in order to approach that level. There are exceptions to every rule, however, and very high protein concentrations can be handled, for example,

perform secondary fractionation: use ion-exchange chromatography, affinity methods, and/or gel filtration
purified protein
insoluble residue
perform polishing step: use HPLC or isoelectric focusing
purified protein

Figure 1.3.4 Purification scheme for membrane-associated and poorly soluble proteins (nonrecombinant). An initial purification can be achieved by isolation of organelles containing the desired protein. Membrane proteins are normally solubilized with a nonionic detergent, although loosely associated proteins may be extracted without detergent at high pH, with EDTA, or with small amounts of an organic solvent such as N-butanol. Normal fractionation procedures may need some modification if the detergent is required throughout to maintain the integrity of the protein.

with two-phase partitioning (Walter and Johansson, 1994). When isolating proteins on a large scale, the volumes being manipulated become of increasing concern, so maximizing protein concentration can be an important aim. The starting extract should be clarified, usually by centrifugation; on a large scale, ultrafiltration methods are becoming more widely used. Pretreatment of certain extracts to remove excessive amounts of nucleic acids, phenolics, and lipids may be necessary in order to obtain an extract that is amenable to standard fractionation procedures.

Fractionation procedures can somewhat arbitrarily be divided into three steps: initial fractionation, secondary fractionation, and polishing. Initial processing, which deals with a large amount of extract that is not all protein, may

BOSTON CENTRAL UNIVERSITY LIBRARY

involve materials that become soiled and unable to be used many times. Consequently, preferred methods do not require expensive reagents or adsorbents such as are used in high-performance liquid chromatography (HPLC). Classic salt fractionation and the less-used organic solvent fractionation can achieve, if not a high degree of purification, a useful level of concentration and removal of much unwanted nonproteinaceous material. Alternatively, a highly selective affinity procedure may be used as the first step, but only if the affinity material is inexpensive to make and/or the extract is a simple, clear solution, as opposed to a turbid whole-cell homogenate.

Secondary processing achieves the main purification, and may involve two or more steps in difficult situations. Ion-exchange and hydrophobic-interaction chromatography, gel filtration, and affinity techniques (see Chapter 8 and Chapter 9) are the main procedures. Finally, it may be necessary to remove traces of contaminants by "polishing," using high-resolution procedures such as reversed-phase HPLC (*UNIT 11.6*) and isoelectric focusing (IEF; *UNIT 10.2 & UNIT 10.4*). Because every protein has unique characteristics, it is impossible to make general statements about procedures to be followed.

MEMBRANE-ASSOCIATED AND INSOLUBLE NONRECOMBINANT PROTEINS

Proteins that are not physiologically soluble can be purified after extracting and removing soluble proteins, thereby achieving a substantial degree of purification at the extraction step (Fig. 1.3.4; also see *UNITS 6.1 & 6.2*). To carry out a purification it is nearly always necessary to obtain the desired protein in a soluble form, which will often require the addition of solubilizing agents such as detergents. Some proteins remain insoluble even with detergent treatment, and so can be substantially purified by removing the soluble fractions. Some membrane-associated proteins become partly solubilized during breaking up of the tissue, and recovery in the particulate fraction may be poor. In such cases it may be best to solubilize the whole tissue by including detergent in the homogenizing buffer. Extraction of insoluble residues using detergents can be done differentially; some proteins are released at low detergent concentration, whereas others require complete solubilization of the membrane fraction. Suitable detergents include nonionic (e.g., Triton) and weakly acidic types (e.g., cholic acid derivatives). Strongly acidic detergents such as sulfate esters (e.g., sodium dodecyl sulfate) usually result in denaturation.

Detergents can be removed either by adsorption of the protein on a column, and subsequent elution without detergent, by use of special detergent-adsorbing beads, or even by extraction with nonmiscible organic solvents in which the detergent partitions. On the other hand, many membrane proteins require the presence of detergent at all times in order to remain in solution and in a native conformation. These include most integral membrane proteins, for example, cytochrome: P_{450}, transmembrane receptors, and transporters. The most sensitive proteins require a particular combination of natural lipids (in addition to the detergent) to maintain structural integrity. Purification methods include most of those used for soluble proteins, but some techniques are not recommended if detergent is needed at all times. For instance, ammonium sulfate precipitation will often cause a detergent-protein complex to come out of solution and float rather than sink on centrifugation—this can be useful, but the "floatate," when redissolved, may have a high detergent content. Hydrophobic chromatography can be very useful, as membrane proteins are naturally hydrophobic.

Integral membrane proteins that are completely insoluble in normal detergents may be solubilized by denaturation using compounds such as sodium dodecyl sulfate and guanidine hydrochloride. Some cross-linked proteins such as elastin are not soluble without disruption of the covalent linkages.

CHAPTER 2
Computational Analysis

INTRODUCTION

The development of the techniques of modern molecular biology, including PCR, cloning, and nucleotide sequencing, has revolutionized the practice of protein chemistry. Whereas the initial phase of detailed study of a new protein activity once involved chemical analysis of the amino acid sequence by Edman degradation of multiple fragments, it is more common today to establish a protein's linear sequence from the nucleotide sequence of the gene that encodes it. While the number of new sequences reported based solely on classical protein sequence analysis has drastically declined, the molecular biology revolution has generated a rapidly expanding collection of new sequence data. The current efforts to sequence specific genomes, including the human genome, in their entirety will undoubtedly lead to further expansion of this information. Because linear sequence information is so readily available, computer methods for analyzing these data have also developed rapidly. This chapter will present methods for deriving important information on possible familial, structural, and functional relationships using only the linear sequence information as input.

As soon as any sequence information is obtained—for example, by running a newly isolated protein through an N-terminal gas-phase sequencer or by dideoxy sequencing a piece of cloned DNA—searches for similarity to other proteins can begin. If the new sequence can be identified as related to that of a known enzyme or gene from another organism, this provides excellent initial confirmation that the protein or gene under study is worthy of further investigations. Conversely, if a match is found to the sequence of a known protein that could only plausibly arise from sample contamination, the study can be halted immediately at considerable savings of time, energy, and resources. *UNIT 2.1* describes procedures for searching sequence databases, provides theoretical background to aid in interpreting the resulting output, and discusses resources for further exploration of sequence relationships.

Once substantial sequence information (particularly a whole gene sequence) is obtained, the most pressing question is what structure it is likely to have. A first step toward answering this question is the analysis of the corresponding amino acid sequence for hydrophobic and hydrophilic regions. Of particular interest are patterns or groupings of hydrophobic residues—typically transmembrane helices, leucine zippers, and amphipathic segments—which can indicate structural and even functional features of the protein. Hydropathy scales, indices designed to quantify the relative hydrophobicity of amino acid residues within a protein, and their application to protein sequences are reviewed in *UNIT 2.2*.

More sophisticated forms of analysis can be used to predict overall protein secondary structure based on linear sequence. The procedures developed for this purpose utilize statistical data that has been compiled over the past 25 years as more and more three-dimensional protein structures have become available. Although these methods are not completely accurate at present, the success rate for predictions is now in the 60% to 80% range. This information is fully adequate to develop hypotheses, design experimental tests, and suggest relationships to known tertiary structures. The prediction of protein secondary structure and folding class are reviewed in *UNIT 2.3*. As well as providing

BOSTON UNIVERSITY MEDICAL CENTRAL LIBRARY

theoretical background and detailing the different predictive approaches, the discussion includes an analysis of the strengths and weaknesses of each approach with respect to different types of proteins (using human hemoglobin β, interleukin 1β, and profilin I as examples) and gives some guidance to obtaining the necessary software.

To perform any method of computer analysis, especially comparisons with other known protein sequences, it is necessary to have facile methods for transfer and capture of a variety of files. Fortunately, standard methodology now exists to perform many of these functions. *UNIT 2.4* provides detailed instructions for the initial steps of getting connected, finding information, and transferring data between computers around the world. Although each university or company will have their own local protocols and systems, and although individuals will need to obtain help from their local computer wizards, *UNIT 2.4* is written to provide directions that are generally applicable to most systems.

Specific recommendations for utilizing various forms of the BLAST programs for sequence searching and comparison are provided in *UNIT 2.5*. Protocols for submission of search commands and search sequence are provided in detail, and examples of search results are presented.

The ultimate goal of any protein chemist should be to understand the relationship between the three-dimensional structure and the functional properties. Future updates to this chapter will address methods to complete the sequence-to-structure algorithm.

Computational Methods for Protein Sequence Analysis

Despite continued advances since the first applications of computers in protein sequence analysis in the late 1960s, computer-assisted biological sequence analysis is still undergoing rapid changes and improvements. With so much activity and growth in the scope and importance of genomic research, the need for efficient biological sequence analysis has become more urgent. Nevertheless, users of computational tools should be aware of the limitations of particular methods. Good results require the user to be able to select the right tools on the basis of some theoretical knowledge and to interpret all results with biological correctness in mind.

This unit is presented as a guide to addressing the issue of what to do with a protein sequence once it is obtained. The practical approach depends on how far the investigation has progressed. If only a short part of the protein (e.g., ~10 to 20 amino acids) has been determined, initial scans of databases to see if there are any significant matches with a known sequence are appropriate. If a complete protein sequence is in hand, it is time to start identifying regions of similarity that resemble functional sites of known proteins.

THEORETICAL BACKGROUND FOR PROTEIN SEQUENCE ANALYSIS

Computer representations of protein sequences are of two basic types: artificial and natural. An example of an *artificial* or symbolic protein sequence is the common 24-letter residue code sequence (ABCDEFGHIKLMNPQRSTVWXYZ*) that represents each amino acid as suggested by the Nomenclature Committee of the International Union of Biochemistry (IUB). This code allows for ambiguities and unknown residue modifications. A *natural* protein sequence, on the other hand, is directly representative of the physical properties of the individual amino acids; for example, in a natural protein sequence the individual elements might be vectors representing the physical characteristics of the amino acid (Robson and Greaney, 1992; Rohde and Bork, 1993). Most molecular sequence analysis algorithms have been designed for the IUB 24-character amino acid representation.

A sequence is an ordered list of elements. Sequences can vary in length, composition, and pattern. The number of possible different protein sequences possible of a particular length is 20^L, where L is the length. The patterns in such sequences are said to constitute the **primary structure** of the protein. In general, proteins have nonrandom sequences that are presumed to be related in the sense that all proteins have evolved from other proteins (Doolittle, 1981, 1986, 1989, 1990). Protein sequences are also subject to **sequence convergence**: different sequences may represent the same native structure of a protein.

Some terms that deal with comparisons of protein sequence data are often used and misused in the literature. **Similarity** is generally used to describe two sequences or structures that resemble one another due to the order of identical residues. **Homology** means that similar sequences or structures resemble one another due to descent from a common evolutionary ancestor. It is important to realize that the sequence analysis tools used to search data bases detect character patterns that resemble portions of the query sequence. This means that they are finding similarities. Homologies are identified through the recognition of correlated structural and functional data in addition to similarity data.

There are three basic types of sequence analyses: listings, traces, and alignments (Kruskal, 1983; Kruskal and Sankoff, 1983). Let $\mathbf{a} = (a_1,..., a_m)$ and $\mathbf{b} = (b_1,..., b_n)$ be two sequences and let E be a set of elementary operations including insertion, deletion, and substitution. An **indel** is either an insertion or a deletion. A **listing** is a finite sequence of operations taken from E that transform **a** into **b**. A **trace** is a one-to-one correspondence of a subsequence of **a** and a subsequence of **b**. An **alignment** of **a** and **b** is a one-to-one correspondence such that each element of one sequence corresponds either to an element of the opposite sequence or to a null element indicating the presence of a gap. The best alignments are obtained when the lengths of **a** and **b** are similar. The correspondence between two nonnull elements is called an **identity** or a **continuation** if the two elements are identical and a **substitution** otherwise. Lines representing the correspondence between two sequences should not cross.

Copyright © 1995 by John Wiley & Sons, Inc.

In the comparison of two different alignments, it is not necessarily the one with the larger number of identities that is better. An alignment with fewer indels (<5%) might be preferable; therefore, some alignment methods set a limit to the number of indels allowed in a given alignment.

Alignments are the most frequently used type of sequence analysis. There are two basic types of alignments: local and global. **Local** alignments are used to identify the most similar common subregions of two sequences. They are especially useful in identifying distantly related sequences. A **global** alignment, on the other hand, attempts a comparison of two sequences in their entirety and, therefore, often misses small subregions of similarity (Pizzi et al., 1991). Global alignments are most useful for comparing highly similar or homologous sequences that are close to one another in length. Two sequences are said to be **homologous** if it can be inferred on the basis of all available information that the sequences have a common ancestor. There are no degrees of homology.

Divergent sequences are those that can be derived from the same sequence, usually by applying the operations in *E*. One way that divergent sequences are identified is by applying scoring matrices. There are several scoring matrices available based on allowable amino acid substitutions found in protein alignments of related proteins (see discussion of scoring matrices that follows). The most common matrices used are the protein alignment matrix (PAM; Dayhoff, 1978); the mutation data matrix (MDM; George, et al., 1990), which is a log-odds version of PAM; and BLOSUM (Henikoff and Henikoff, 1993), which incorporates the consideration of the conversation of function data between aligned proteins. It should be noted that the restriction of global alignments to operations in *E* would fail to align two sequences containing **transpositions**, in which segments of the protein sequence have been reordered within the sequence (Burks, 1990; States and Boguski, 1990).

The similarity of two biological sequences is usually specified by either a similarity measure or a distance measure. **Similarity measures** typically compute the score for an alignment using an optimizing function that rewards identities and penalizes nonidentities and gaps. **Distance measures** are usually defined as functions that satisfy the axioms for a metric function:

Distance(**a**,**b**) = 0 if and only if **a** = **b**;

Distance(**a**,**b**) = distance(**b**,**a**);

Distance(**a**,**b**) ≤ distance(**a**,**c**) + distance(**c**,**b**).

Distance functions can be thought of as minimizing differences to find the best alignments, whereas similarity methods search for the best alignments by maximizing similarities. "All problems known to be solvable with distance methods can be solved with similarity methods" (Waterman, 1989). The metric approach appeals to the geometric intuition: sequences can be thought of as points in space, and any three distinct points **a**, **b**, and **c** form a triangle *ABC* that satisfies the rules above. The smaller the distance between two points, the greater the similarity of the sequences.

There are many factors to be considered in protein sequence comparison (Hodgman, 1992). Amino acids are not equally abundant in protein sequences. Moreover, proteins fold into structures having well-conserved hydrophobic interior residues and poorly conserved exterior residues. Indeed, there is a descending order of residue conservation: active-site residues > crucial folding residues > internal packing residues > surface residues. Some residues have preference for position, secondary structure, and substitution; for example, active-site residues are often found in loops that are part of a supersecondary unit and may be partially buried. An identity of >25% implies similarity of function, whereas 18% to 25% identity may indicate similarity of structure or function. The latter range is within the "Twilight Zone" (15% to 25% identity) that, according to Doolittle, arises in the theory of protein evolution (Doolittle, 1986).

Alignment methods usually have a specific region of applicability (Taylor, 1988). For example, pairwise alignment is most applicable at high levels of identity (~70%); consensus methods (~45%), template methods (~25%), and structure prediction methods are applicable at even lower levels of identity. These ranges take into account the fact that even two unrelated or random sequences over 100 residues long may show identity in the range of 20%.

Two complementary properties of sequence comparison methods are sensitivity and specificity (States and Boguski, 1990). **Sensitivity** is the ratio of false negatives to the sum of true positives and false negatives; **specificity** is the ratio of true positives to the sum of true positives and false positives.

The goal of this unit is to provide some

starting points for the analysis of protein sequence data. A theoretical review of principles is complemented by practical examples of computer methods for protein sequence analysis that were done using the GCG package of programs (Genetics Computer Group, 1994). There are many other commercial packages for IBM-compatible computers, Macintoshes, and UNIX workstations that have similar capabilities. There are also many public domain software packages available over the Internet that have identical or enhanced functionalities (see Table 2.1.1). When starting to assemble programs for protein sequence analysis, one is strongly advised to browse the Internet before purchasing. The CD-ROM version of *Current Protocols in Protein Science* also includes the Entrez and MACAW multiple sequence alignment programs from the National Center for Biotechnology Information (NCBI) at no additional charge. *UNIT 2.2* describes the analysis of linear protein sequence with respect to hydrophobic/hydrophilic characterization that can suggest structural or functional segments. *UNIT 2.3* presents methods for the prediction of secondary structural features of linear protein sequences.

MATRIX METHODS FOR SEQUENCE COMPARISON: DOT PLOTS

Many computer-based sequence comparison methods rely on matrix methods (Fitch, 1966, 1969; Gibbs and McIntyre, 1970; McLauchlan, 1971, 1972; Maizel and Lenk, 1981; Argos, 1987; Landau et al., 1988, 1990). Pairwise comparison of two sequences can be represented in its simplest form by a matrix that is the logical product of the two sequences: if a corresponding pair of elements is identical, then the matrix element at the intersection of the row and column is marked true (dot); if the pair is different, then the matrix element is marked false (blank). The result is a visualization of the similarity of the two sequences.

In dot-plot matrix displays, a run of identities will be seen as a continuous diagonal segment within the matrix. Discontinuities along diagonals with horizontal shifts to parallel lines are interpreted as indels and indicate the need for gaps in any alignment. If the two sequences being compared are identical, the matrix will reveal any internal repeats and the main diagonal will be filled in. Self-comparisons always result in symmetrical dot plots.

Another commonly used dot-matrix method compares fixed-length segments (**windows**) of the sequences instead of individual residues. See Staden (1994a-d) for a description of how to use SIP, a program based on dot-matrix plots.

A **palindrome** is a subsequence that remains the same after being reversed. On a dot plot, palindromes are displayed as segments perpendicular to the main diagonal of the matrix. Palindromes are not usually relevant to protein sequences. In RNA and DNA sequences, a palindrome is defined as an inverted, self-complementary region such as ACTGATATCAGT.

More sophisticated comparisons have been defined on dot matrices that filter out isolated dots or small segments as noise. The **stringency** of the similarity determines the amount of data that will be filtered out before the matrix is displayed or undergoes further processing. In this case, the matrix elements are filled in with weighted numerical scores instead of simple identity values, and the result is plotted as a surface to visualize the regions of greatest similarity. Dot-matrix methods remain an active area of research (Streletc et al., 1991; Landes et al., 1993; Nedde and Ward, 1993).

Dot plots are the simplest form of sequence comparison using a matrix display. These graphical methods allow quick observation of the level and extent of similarity between two sequences. For example, a comparison of horse and rat serum albumin protein sequences from the SWISS-PROT protein database is summarized in Figure 2.1.1.

Dot-plot analysis is done in two phases: pairwise sequence comparison to generate a matrix of similarity values is followed by generation of the graphic display. The GCG package implements this process by using two programs—COMPARE and DOTPLOT—to generate the dot-matrix plot. COMPARE does a pairwise analysis to define positions of similarity between the two sequences. The parameters to be varied are (1) window size, or the number of residues to be compared, and (2) stringency, or the minimal number of matches per window to score a dot. DOTPLOT generates the graphic matrix display of the COMPARE analysis (Fig. 2.1.1).

SEQUENCE SIMILARITY SEARCHING

Once a small portion of protein sequence data from an unknown sample has been generated, the immediate impulse is to ask what other proteins in the database does the unknown resemble, and how similar are the sequences. Several available tools can help answer these

PANNING LIBRARY

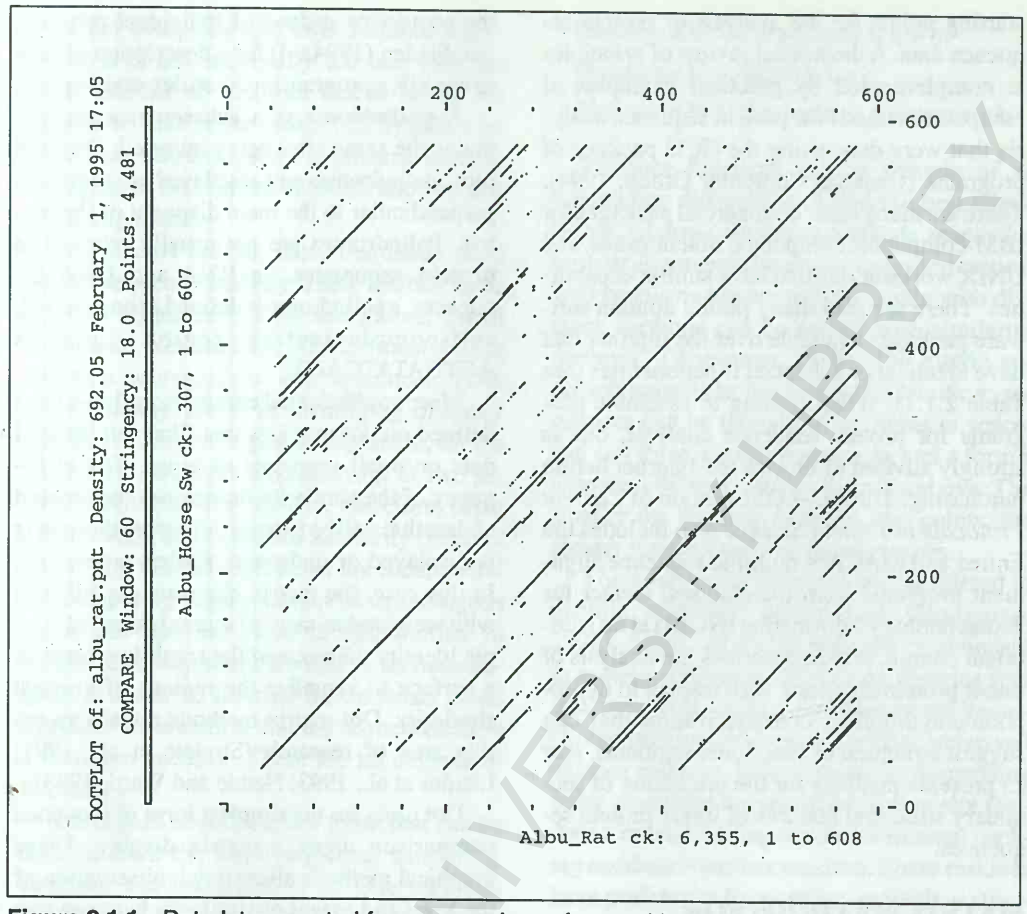

Figure 2.1.1 Dot plot generated from comparison of rat and horse albumin protein sequences. The continuous diagonal line of identity traverses the middle of the matrix. Regions of similarity between the two sequences appear as lines parallel and offset to the line of identity. Axis label takes the form filename ck: checksum_value start_position to end_position.

questions. Most commercial sequence analysis packages contain programs for performing pairwise alignments of protein sequences. The most popular tools for searching databases, FASTA (FAST All) and BLAST (the Basic Local Alignment Search Tool), are included in commercial sequence analysis suites and are also freely available to be downloaded to a local computer to be used in a stand-alone manner or as network services.

BLAST Database Searching

The program BLAST, which is available from the NCBI, conducts rapid searching of sequence databases (Altschul et al., 1990). The program searches for similarity between a query sequence and sequences in a nucleotide database (using BLASTN) or peptide database (using BLASTP). Two versions of the program are available: (1) a version that will run on a local workstation and (2) client software that connects a local computer via the Internet to a high-speed search engine located at the NCBI. The latter accesses the most recent versions of sequence databases available.

BLAST uses a word/dictionary approach to compare fixed-length "words" from the query sequence against the dictionary of words from the database searched. This program is an excellent choice for quickly screening for exact matches—for example, when the end of a new protein has been sequenced. A word of caution is, however, in order: BLAST can create enormous files, especially if the query sequence has repeated residues or is similar to a repeated motif in the databases. The BLAST output file contains (1) the sorted match statistics, probability measure of a random match and the number of matched regions; (2) the alignments generated for the query and the matched sequence region (shown in Fig. 2.1.2); and (3) a copy of the search parameters (not shown). The example in Figure 2.1.2 shows output from a BLAST search conducted using a sequence fragment from an unknown mammalian blood protein as a query against the nonredundant

Figure 2.1.2 BLAST output table and alignment for an unknown mammalian blood protein. The Query is the sequence of interest and the sbjct is the sequence region found in the database that matches the query. Note that in searches of the nonredundant databases at the NCBI, matches are found between the test sequence and the translation of mRNAs in GenBank. Important similarities have small probability scores, i.e., $P(N) < 10^{-3}$. This analysis suggests that the unknown is an albumin, but it is not identical to any known sequence.

protein sequence database maintained at the NCBI. This database contains a compilation of protein sequences found in all of the molecular sequence databases with duplicate sequences removed. Figure 2.1.2 presents a table of the top 20 highest similarity scoring sequences and the best alignment.

FASTA Database Searching

FASTA conducts a Lipman and Pearson (1985) search for similarity between a query sequence and any FASTA-formatted database or group of sequences collected in a database by the user. FASTA is a program developed for fast searching using an algorithm that allows for the insertion of gaps during the alignment phase. This approximates evolutionary insertions and deletions during divergence. However, the gaps are generated to maximize the number of aligned residues. FASTA does a good job of generating a global alignment for a sequence.

Figure 2.1.3 and Figure 2.1.4 present results from a FASTA search of the SWISS-PROT database with a short sequence fragment from an unknown mammalian blood protein. The FASTA output contains (1) a histogram that shows the distribution of relevant word matches found between the query sequence and the database searched; (2) the match statistics; and (3) the alignments generated for the query sequence and the matched sequence region.

Figure 2.1.3 FASTA histogram from a search of the SWISS-PROT database for sequences similar to a fragment from an unknown mammalian blood protein. Numbers of windows at each *init1* score are plotted. Note that there are six highly significant alignments, as well as several sequences (those with *init1* scores in the 48 to 56 range) that represent protein sequences from more distantly related species.

There are three similarity scores presented in the output from FASTA: *init1*, the highest similarity score allowing conservative substitutions; *initn*, the highest score generated by linking nonoverlapping regions; and *opt*, the score for the best alignment presented. In practice the histogram would be used to determine how many sequences have highly significant levels of similarity. The table of scores allows one to decide quickly how many and which sequence alignments should be viewed.

ALIGNMENT METHOD CONSIDERATIONS

Dynamic programming is a different matrix method that is used to find the optimal global alignment of two sequences (Needleman and Wünsch, 1970; Sellers, 1974; Pearson and Miller, 1992; Panjukov, 1993). Let **a** be a sequence of length *m* and let **b** be a sequence of length *n*. Let **D** be the working matrix. Then, given a predefined scoring function, the basic steps of the alignment algorithm (Doolittle, 1986) are as follows. Assign the scores for all exact matches to the corresponding matrix el-

ements. Transform the matrix by beginning with element D_{mn} and adding its value (less any gap penalty) to D_m^{-1}, $_n^{-1}$ and all the elements directly above it or to its left. Next, select the matrix element in column $m-2$ and above row $m-1$ that contains the largest score and repeat the summing procedure. Repeat the previous step until the entire matrix is transformed. Next, determine the path from the largest score in the matrix back toward the bottom right-hand corner. The path, with any gaps as indicated by off-diagonal moves, is then used to align **a** and **b**.

This matching algorithm is used in most global alignment programs, which vary primarily in the sophistication of the scoring functions (similarity or distance). Note that this method assumes (incorrectly) that each residue has equal importance, and it ignores sequential constraints.

Local alignments are usually found using some version of the Smith-Waterman method (1981), which applies when common regions are being sought in two sequences whose similarity is unknown or limited to a few regions, as is the case in database searches. The algorithm usually produces a single highest-scoring alignment with respect to the operations in E, although it has been successfully extended to produce the second-best and other alignments (Barton, 1990, 1993; Waterman and Eggert, 1991).

In its simplest form (Barton, 1993), the local alignment method is as follows. Given two sequences **a** and **b**, and a working (comparison) matrix **H**, the matrix elements of **H** are filled in by applying a scoring rule: the score assigned to a matrix element H_{ij} is either zero or the maximum value of any of the three scores of its neighbors and predecessors that lie directly above, diagonally to the left, or directly to the left of H_{ij}, adjusted for gaps or substitution of residues. The maximum element in **H** is found and traced back through the matrix to find the alignment.

SCORING MATRICES

Scoring matrices (George et al., 1990; States and Boguski, 1990), such as the PAM, BLOSUM (Henikoff and Henikoff, 1993), and related MDM matrices (Dayhoff, 1978), are based on the compilation of frequencies of amino acid substitution in a set of homologous sequences. The data are used as an amino acid transition probability matrix. Increasing powers of the matrix correspond to increasing divergence. Lower powers are used for sequences that seem closely related and higher powers for those that are not so obviously related. Thus, PAM250 represents a matrix with 250 accepted protein mutations per 100 amino acids. The scoring matrix method has greatly improved the quality and sensitivity of alignments; however, it does have the deficiency that it ignores structure and the corresponding sequence constraints which are significant for predicting structure.

Not all sequence comparison methods are

BOSTON UNIVERSITY LIBRARY

matrix methods. Programs such as FASTP and FASTN are representative of hash-coding methods (Dumas and Nunio, 1982; Wilbur and Lipman, 1983; Lipman and Pearson, 1985; Pearson, 1990, 1994). The methods are based on fast table lookups of subsequences of a target sequence using **hash functions**. Hash functions transform strings in numbers that serve as pointers into a table containing further information. Thus, a fixed-length subsequence (or *k*-tuple) of one sequence can quickly be checked for occurrence in another sequence after a hash table of *k*-tuples and their positions in the sequence is constructed for each sequence. FASTP focuses on regions having the highest density of identities and uses the PAM250 matrix.

Readers are referred to Pearson (1994) for an introduction to using FASTA for comparing both DNA and protein sequences. The RDF2 and RSS programs for testing the statistical significance of FASTA alignments are also discussed.

Other methods for sequence comparison include **finite state machines** that are capable of recognizing regular expressions, and various statistical approaches (States and Boguski, 1990; Tyler et al., 1991; Allison et al., 1992; Brendel et al., 1992). Regular expressions are formulas such as (**a** + **b***)**c**, which represents the set of all strings that begin with the letter **a** *or* zero or more **b**'s *and* followed by a single **c**. Complicated patterns can be constructed and detected in sequences using the finite state method. Statistical approaches include the database-searching program BLAST (see above section on BLAST database searching), which approximates gapless alignments that optimize local similarity on the basis of maximal segment pairs. The BLAST strategy is to search for only those segment pairs that contain a word pair whose comparison score exceeds some threshold. It uses the PAM120 scoring matrix to allow for conservative substitutions of residues in a comparison.

Statistical methods for sequence alignment (Karlin et al., 1988, 1989, 1991; Brendel, 1992; Pevzner, 1992; Mrazek and Kypr, 1993; Staden, 1994a-d) consider the statistical significance of a variety of protein sequence properties. Such properties include the relative composition of a sequence with respect to residue types; anomalous clusters, runs, and periodic variations of charge; internal repeats; local periodicities that might indicate regularity of structure; and the relative spacings of certain residue types. For a description of routines for plotting hydrophobicity, charge, and hydrophobic moments using the program PIP, see Staden (1994a-d).

In addition to the methods described above, interest in the development of theory and tools for linguistic (formal grammar) analysis of biological sequences is growing (Collado-Vides, 1991; Michaels et al., 1993; Searls, 1993).

The next level of sequence analysis is the simultaneous comparison of more than two sequences, as described in the following section on Multiple Alignments.

MULTIPLE ALIGNMENTS

Once a group of potentially homologous sequences has been identified, the next step could be to do a **multiple alignment** that compares the new sequence with the group of sequences determined to have highly significant similarities. There are several programs that will do multiple alignments. PILEUP from the GCG package does a good job with closely related sequences in an automated fashion. MACAW from NCBI, LINEUP from GCG, and DSCE (De Rijk and De Wachter, 1993) allow the investigator to generate an alignment manually. (The CD-ROM version of *Current Protocols in Protein Science* includes MACAW and Entrez from NCBI.)

Figure 2.1.5 demonstrates a multiple alignment generated using PILEUP from five high-scoring albumin sequences in the SWISS-PROT database identified from the FASTA analysis (Fig. 2.1.4). PILEUP performs a cluster analysis based on pairwise comparisons of each sequence to be aligned. As well as the multiple alignment (Fig. 2.1.5), PILEUP produces a dendrogram (not shown) that displays the clustered relationships between the sequences. The dendrogram is not a phylogenetic tree, but a graphical representation of the clustered similarity statistics.

After the multiple alignment is generated, one can begin to infer relationships between conserved regions and function or structure. The program Pro_Anal (Eroshkin et al., 1993) and the program for fast protein block searches (Fuchs, 1994) can help in this process. Programs like OBSTRUCT (Heringa et al., 1992) are useful in identifying clusters of protein sequences on the basis of structural and sequence similarity criteria. Kanaoka et al. (1989) have described a process of aligning protein sequences on the basis of hydrophobicity. Livingstone and Barton (1993) describe a strategy to generate multiple alignments for hierarchical analysis of residue conservation.

Figure 2.1.5 Multiple alignment of mammalian blood proteins using PILEUP. The first 400 residues of five high-scoring sequences identified from FASTA analysis (Fig. 2.1.4) are aligned.

Similarly, the program PIMA (Smith and Smith, 1992) uses an algorithm that takes advantage of secondary structure features to determine gap penalties during the multiple alignment process. Depiereux and Feytmans (1991) have used simultaneous multivariate multiple alignment methods to reveal a correspondence between physiochemical profiles and structurally conserved regions.

The multiple alignment programs described above take advantage of pairwise comparison algorithms and are subject to their limitations. Alignment algorithms that use a rigorous consideration of more than three sequences at once are computationally infeasible for most labs. Although some speed improvements have been obtained for the optimal alignment of three sequences simultaneously (Murata et al., 1985; Gotoh, 1986), new methods have to be developed for multiple sequence alignment. The earliest methods were sequence editors for interactive alignments. See Pearson and Miller

BCM MEDICAL CENTER LIBRARY

(1992) for a discussion of considerably improved dynamic programming algorithms for sequence analysis.

Multiple sequence alignment tends to be order-sensitive. A sequence of pairwise comparisons may not lead to the best overall alignment for a given set of sequences because the sequences are not independent (States and Boguski, 1990)—that is, they are not necessarily equidistant from a common ancestor.

The **consensus sequence** approach to multiple sequence alignment (Waterman, 1989, 1990; Waterman and Jones, 1990; Day and McMorris, 1993) is based on the construction of a single sequence that can be used to align all other given sequences; the sequence is determined by an iterative process of alignment followed by consensus sequence modification. A consensus residue can be stringently defined from a multiple alignment when the content of a column is represented by a single amino acid at that position.

There are many multiple alignment algorithms—too many to describe here. A list of available sequence similarity and alignment software can be accessed via the Internet as described in the section below on Internet Resources.

Once sequences have been aligned, the quality of the alignment should be assessed. It is clearly important to distinguish between chance similarities and true sequence similarities. One method for estimating the quality or **statistical significance** of an alignment (Doolittle, 1986) is to compare the alignment score with the mean score of a set of randomized sequences that are permutations of the original sequences and which preserve their length and relative composition. The further the alignment score is from the mean of the randomized set, the more confident we can be in the alignment. A possible objection to this data shuffling or permutation method is that the permuted sequences are not like real protein sequences (i.e., permuted sequences are unlikely to fold like real proteins).

Other methods (States and Boguski, 1990) include the following: McLachlan's (1972) "double matching probability" function, which is used to compute the frequency scores in infinite random sequences of the same composition as the given sequences; Reich and Meiske's stochastic random sequence model for determining the significance of window scores in dot-matrix analysis (Reich and Meiske, 1987); and Argos' significance tests (Argos and Vingron, 1990), based on actual protein sequences instead of the randomized sequences used by McLachlan (1972). Despite efforts to determine the quality of alignments, it remains true that low statistical significance does not always imply a lack of biological significance (Collins and Coulson, 1990).

Another important aspect of alignments is the **accuracy** of the original molecular sequence (States, 1992). Errors can be introduced in molecular sequence data in random or biased ways. The translation of nucleic acid sequences into amino acid sequences is very sensitive to indel errors: an error rate of 1% can lead to a frameshifting error in reading frames longer than 24 amino acids. Empirical estimates of sequence accuracy in current databases have revealed a rate of 3 to 5 errors per 1000 bases.

CLUSTER METHODS AND TREES

Once a multiple alignment has been performed and regions of common similarity have been identified among the proteins, the question of evolutionary distance will arise. There are several programs for determining the level of divergence between a group of sequences. Some are available over the Internet via the World Wide Web (WWW; see also Internet Resources section). The programs DISTANCES and GROWTREE from the GCG package (Genetics Computer Group, 1994) calculate pairwise distance measures and plot a dendrogram of those measures. The programs depend on an accurate multiple alignment of the sequences involved. This means that the multiple alignments should be examined carefully and then edited as necessary to incorporate additional knowledge that might be available about the structure or function of the proteins. Figure 2.1.6 shows the table of pairwise phylogenetic distances calculated by DISTANCES for the top nine albumins identified from the FASTA analysis (Fig. 2.1.4), and the phylogram produced by GROWTREE is shown in Figure 2.1.7.

The purpose of protein sequence comparison is to learn more about the structure, function, and evolution of proteins. It is known that different proteins and different parts of proteins change at characteristic but unequal rates in the course of evolution (Doolittle, 1986). Binding sites and catalytic units are conserved independently of their position, whereas surface regions change faster than buried regions. In addition, entire domains of a genome are subject to a number of editing operations such as domain joining, swapping, and reordering (States and Boguski, 1990). Thus, homologies

Figure 2.1.6 Evolutionary distance table for mammalian blood proteins calculated using the GCG DISTANCES program. Corrections to the calculations were done using the Kimura protein method as described in the GCG manual (Genetics Computer Group, 1994). The matrix values represent the number of matches between each pair of sequences divided by its length (999.9 = identity). These data were used to generate the GROWTREE phylogram presented in Figure 2.1.7.

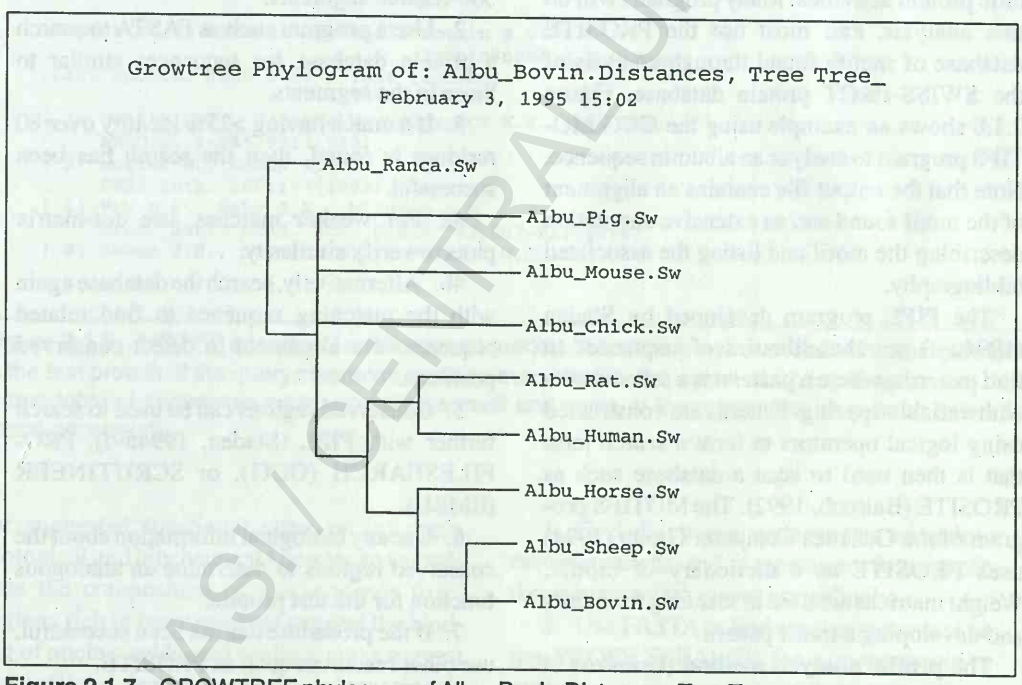

Figure 2.1.7 GROWTREE phylogram of Albu_Bovin.Distances, Tree Tree_1. Results of graphical cluster analysis of the distance data presented in Figure 2.1.6 are shown. In this representation sequences with the least divergence have the shortest branches.

BCU LASI / CENTRAL UNIVERSITY LIBRARY

might be found between entire proteins or just between certain parts of proteins.

IDENTIFICATION OF FUNCTIONAL SITES

Sequence comparisons are used to test for homology and to find functional sites and motifs. The goal is to establish structure and function for parts of an unknown sequence using known homologous or analogous (i.e., similar, but not homologous) sequences as sources of additional information. The goal is to obtain answers to questions of what functions the protein has and what its structure is. There are several paths the analysis can take.

One approach that will reveal much about potential functional sites in the protein is to look for motifs. **Motifs** are defined in three ways: as consensus patterns of amino acids that correspond to regions of proteins containing the common residues; as the excised alignment of several sequences that contain the motif for use as a database discriminator; or as a single representative sequence (States and Boguski, 1990; Parry-Smith and Atwood, 1992). Motif searches are usually done using a program that takes advantage of a dictionary of sequence patterns which have been identified with specific protein activities. Many programs will do this analysis, and most use the PROSITE database of motifs found through analysis of the SWISS-PROT protein database. Figure 2.1.8 shows an example using the GCG MOTIFS program to analyze an albumin sequence. Note that the output file contains an alignment of the motif found and an extensive annotation describing the motif and listing the associated bibliography.

The PIPL program developed by Staden (1994a-d) searches libraries of sequences to find patterns, where a **pattern** is a set of motifs with variable spacing. Patterns are constructed using logical operators to form a search term that is then used to scan a database such as PROSITE (Bairoch, 1992). The MOTIFS program of the Genetics Computer Group (1994) uses PROSITE as a dictionary of motifs. Weight matrices are used in scanning for motifs and developing a motif pattern.

The **profile analysis method** (Gribskov et al., 1988, 1990; Gribskov, 1994) also involves weight matrices and is related to the consensus method. It is used for sensitive similarity matching, for homology seeking, and for scanning databases for motifs. It measures the similarity between a given sequence, called the **target**, and a group of aligned sequences called the **probe**. The alignment of the probe uses a modified MDM_{78} mutational matrix. The matrix values of the profile are computed column-wise as the weighted average of the score for each residue at that position in the aligned sequences and the residue represented by the column of the profile; a row of the profile is the weighted average of the rows in the MDM_{78} table corresponding to the aligned residues at that position. The result is the set of properties that tend to be conserved at particular positions along the sequence. For detailed information on using profile analysis software to scan for homologies and motifs, see Gribskov (1994). A relatively new homologous sequence retrieval program (using the BLOSUM250 matrix) is dFLASH, which is available by E-mail server (Rigoutsos and Califano, 1994).

There are many ways to proceed in computational analysis of new sequences. Each will provide a wealth of information to guide further laboratory experimentation. The following procedures illustrate two approaches to protein sequence analysis and can be adapted as required.

Hodgman (1992) suggests the following protocol for protein function determination:

1. Split sequences into overlapping 200- to 300-residue segments.
2. Use a program such as FASTA to search a protein database for sequences similar to those in the segments.
3. If a match having >25% identity over 80 residues is found, then the search has been successful.

4a. For weaker matches, use dot-matrix plots to verify similarity.

4b. Alternatively, search the database again with the matching sequence to find related sequences for alignment to detect conserved positions.

5. Conserved regions can be used to search further with PIPL (Staden, 1994a-d), PROFILESEARCH (GCG), or SCRUTINEER (EMBL).
6. Use any biological information about the conserved regions to determine an analogous function for the test protein.
7. If the procedure has not been successful, use other resources such as PROSITE.
8. Check that all results are biologically credible.
9. If all else fails, (a) look for repeats within the sequence itself: if there are only two or three, it usually indicates that the protein has a repeated functional domain; (b) examine the distribution of particular amino acids or classes

****************************************
* ATP/GTP-binding site motif A (P-loop) *
****************************************

From sequence comparisons and crystallographic data analysis it has been shown
[1,2,3,4,5] that an appreciable proportion of proteins that bind ATP or GTP share
a number of more or less conserved sequence motifs.  The best conserved of these
motifs is a glycine-rich region, which probably forms a flexible loop between a beta-
strand and an alpha-helix.  This loop interacts with one of the phosphate groups of
the nucleotide.  This sequence motif is generally referred to as the 'A' consensus
sequence [1] or the 'P-loop' [5].

There are numerous ATP- or GTP-binding proteins in which the P-loop is found.We list
below a number of protein families for which the relevance of the presence of
such motif has been noted:

A list of proteins containing the motif has been omitted for brevity.

Not all ATP- or GTP-binding proteins are picked-up by this motif.  A number of
proteins escape detection because the structure of their ATP-binding site is
completely different from that of the P-loop.  Examples of such proteins are the
E1-E2 ATPases or the glycolytic kinases.  In other ATP- or GTP-binding proteins
the flexible loop exists in a slightly different form; this is the case for
tubulins or protein kinases.  A special mention must be reserved for adenylate
kinase, in which there is a single deviation from the P-loop pattern: in
the last position Gly is found instead of Ser or Thr.

-Consensus pattern: [AG]-x(4)-G-K-[ST]
-Sequences known to belong to this class detected by the pattern: a majority.
-Other sequence(s) detected in SWISS-PROT: in addition to the proteins listed above,
the 'A' motif is also found in a number of other proteins. Most of these proteins
probably bind a nucleotide, but others are definitively not ATP- or GTP-binding
(as for example chymotrypsin, or human ferritin light chain).

Figure 2.1.8 MOTIFS analysis of an albumin sequence. This example shows results for a single motif found in the test protein. If the query sequence contains many motifs, the output can be quite extensive. Note that a long table of sequences which contain the motif and some of the references have been deleted due to space constraints.

for suggested functional sites; or (c) apply biological and biochemical knowledge to evaluate the composition of the sequence (e.g., regions rich in basic residues suggest the binding of nucleic acids, and acidic regions suggest generalized protein-protein interactions). Structure determination can begin with the Chou-Fasman (Chou and Fasman, 1974) or Garnier-Osguthorpe-Robson algorithm (Garnier et al., 1978); both are discussed in *UNIT 2.3*.

States and Boguski (1990) offer another scheme for the analysis of protein sequences:

1. Find all intrasequence repeats using dot-matrix methods, and, if repeats are found, split the sequence into pieces accordingly.
2. Use FASTA to find similar sequences or use PROFILESEARCH for a more sensitive search.
3. Compare the sequence to known motifs, for example, in the PROSITE database.
4. Search for hydrophobic segments using the Kyte-Doolittle (1982) method and for α helices and β strands using the hydrophobic moment (see *UNITS 2.2 & 2.3*).

BOTANY / CENTRAL UNIVERSITY LIBRARY

5. If step 1 or 2 was successful, then search for helices using the variation moment.

6. If step 1 or 2 was successful, calculate the hydrophobic correlation to estimate similarity.

7. Keeping in mind that the results will be only 55% to 65% accurate, compare the outputs of several secondary structure prediction methods with information from all available homologous sequences.

8. For antibodies, identify possible antigenic regions using hydrophilicity plots and antigenicity index plots.

9. Look for unusual features such as leucine zippers; this can be done with any program, such as PROSITE, that takes advantage of a dictionary of motifs.

10. Determine potential sites of cleavage by various chemicals; cleavage sites can be predicted by computer methods and verified experimentally.

INTERNET RESOURCES

The Internet has become an important resource in bioinformatics. There are new tools that make it easy to locate the latest software and databases. Since 1994 a new Internet-based network of hypertext tools that takes advantage of the World Wide Web (WWW) has emerged. To enter the WWW, you will need a network hypertext browser such as MOSAIC. Versions of MOSAIC, which was originally developed by the National Center for Supercomputer Applications (NCSA), are now freely available for most commonly used laboratory computers. If your local computer is connected to the Internet and your system has file transfer protocol (FTP) capability, connect to ftp.ncsa.uiuc.edu and log in under the username anonymous to retrieve a copy of MOSAIC for the computer you use most often. Once you have MOSAIC or another WWW browser running, we recommend connecting to the Australian National University's Bioinformatics server (http://life.anu.edu.au) and selecting "Molecular biology" from the menu. Table 2.1.1 reproduces the list of resources available. Another current resource of hyperlinks is available through the author using MOSAIC or Netscape at the George Mason Computational Biology Resource (http://www.science.gmu.edu/~michaels/comp_bio).

As indicated by that list, there is a tremendous number of resources available on the Internet. In addition, there are many useful text and program files available by FTP that are of interest to molecular biologists and other scientific and medical researchers. A few are presented here. For a listing of molecular sequence and related software, get the *Catalogue of Molecular Biology* from Genethon by connecting via ftp ftp.genethon.fr and entering cd pub/resig/catalogu then mget bio.catal*.

Amos Bairoch's bibliographic database on sequence analysis (*seqanalref*), the Listing of Molecular Biology Databases (*LiMB*), a directory of researchers who apply artificial intelligence (AI) techniques to problems in molecular biology (*aimbdb*), and many other valuable files can be found using anonymous FTP to ncbi.nlm.nih.gov. Bairoch's lists of molecular biology e-mail, FTP, and BBO servers are also available using anonymous FTP: type ftp expasy.hcuge.ch, then cd databases/info, then mget serv_ema.txt serv_ftp.txt serv_bbo.txt.

For a copy of the *BIOSCI FAQ*, a collection of Frequently Asked Questions, use ftp net.bio.net, then cd pub/BIOSCI/doc and get biosci.FAQ.

Hydrophobicity Profiles for Protein Sequence Analysis

INTRODUCTION

Seminal work by Anfinsen et al. (1961) showed that the three-dimensional structure of a protein is determined by its amino acid sequence. Thus, significant effort has been aimed at unraveling the complex relationship between sequence and structure. Although there is no immediate prospect of a general solution to the protein folding problem, stepwise empirical methods have been developed that analyze protein sequences and successfully provide predictive results concerning protein structure.

The work of Kauzmann (1959) determined that hydrophobic interactions are a major force in protein folding. Accounting for the hydrophobicity of amino acids within a protein is thus the first step toward understanding protein folding (Tanford, 1980). Hydrophobicity studies have resulted in a wide range of **hydropathy scales**, indices that attempt to quantify the relative hydrophobicity of the amino acids. The actual hydrophobic content attributed to each amino acid is dependent on the methodology used to estimate it and may vary from scale to scale. Some scales are based solely on physicochemical measurements such as the free energy of side-chain transfer (Nozaki and Tanford, 1971; Wolfenden et al., 1981). Other scales are based on statistical analysis of three-dimensional structures (Chothia, 1976; Rose et al., 1985). In addition, scales can be a combination of both procedures (Kyte and Doolittle, 1982). The general observation that hydrophobic residues tend to be buried in the interior of the protein whereas hydrophilic residues prefer to be exposed to solvent is predominant in all scales.

Generating a hydropathy profile requires two things: (1) the primary structure and (2) the hydropathy scale. The primary structure can be obtained by translating the cDNA or by sequencing the protein. Hydropathy profiles for a protein are obtained by averaging or combining the hydrophobicity or hydrophilicity of an individual amino acid (taken from a particular hydropathy scale) with the values of several neighboring residues along the protein sequence, then plotting the local averages or sums against the amino acid sequence. In such hydrophobicity plots, regions of hydrophobicity and hydrophilicity appear as maxima and minima, respectively. A fundamental use of hydropathy profiles, therefore, is predicting the overall hydropathy (hydrophobicity or hydrophilicity) of a protein from its amino acid sequence. The distribution of local hydropathy values can provide insight into the overall folding pattern of the protein (see Applications).

Numerous procedures have been developed for calculating the hydropathy profile of a protein based on the free energy of side-chain transfer from water or vacuum to an organic solvent (Nozaki and Tanford, 1971; Tanford, 1980; Wolfenden et al., 1981; Fauchere and Pliska, 1983). The procedures differ primarily in the hydropathy scale used, and the different hydropathy scales have arisen, in part, to address specific applications. For example, the hydrophilicity scale of Hopp and Woods (1981) was developed to locate antigenic segments; the Goldman, Engleman, and Steitz (GES) scale (Engleman et al., 1986) was developed to identify transmembrane regions in a protein.

Although individual scales were developed for different purposes or by alternative procedures, significant similarity exists in the resultant profiles. Most hydropathy plots show similar distributions of minima and maxima in the sequence profiles. In Figure 2.2.1, the result of applying the most widely used hydrophobicity scale, that of Kyte and Doolittle (1982), is compared to results of applying the scales of Hopp and Woods (1981) and Eisenberg (1984) to hen egg white lysozyme. The similarity in profiles is partially due to the fact that maxima and minima often reflect secondary structure elements; regions of hydrophobicity and hydrophilicity can be correlated with β sheets and β turns, respectively (Kuntz, 1972; Roy and Rose, 1980).

Hydropathy profiles can be used to examine the surface features of proteins in order to generate hypotheses that can be confirmed experimentally. For example, such analyses received widespread use in the prediction of antigenic and other interaction sites on proteins. Furthermore, when used in conjunction with other secondary structure prediction algorithms (see *UNIT 2.3*), hydropathy profiles have been shown to correlate well with α-helical, turn, and β-sheet propensities. As such, they have proved to be invaluable for predicting protein secondary structure. The most extensive use of hydropathy profiles has been for

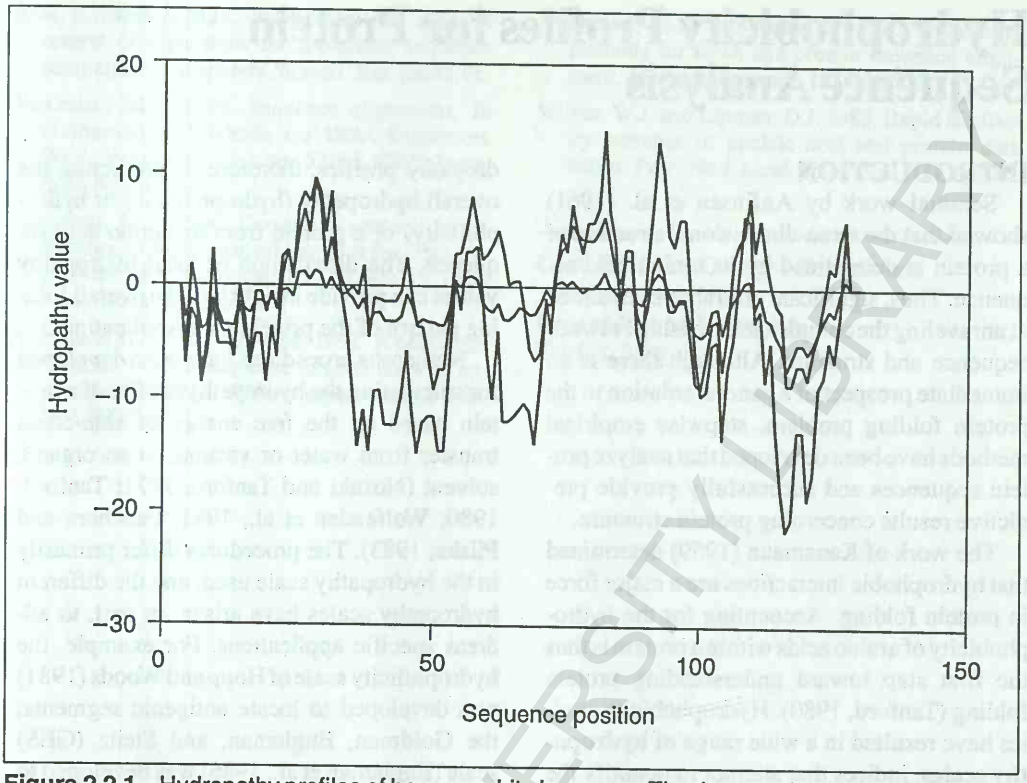

Figure 2.2.1 Hydropathy profiles of hen egg white lysozyme. The three profiles were created with the Kyte and Doolittle, the Hopp and Woods, and the Eisenberg scales using a scanning window of 7 amino acids. The Hopp and Woods scale was modified as described in the text to match other hydropathy scales.

deducing transmembrane regions in membrane proteins.

Previous reviews describe systematic evaluations of hydropathy procedures and provide criteria for selecting the most appropriate amino acid hydropathy scale (Engleman et al., 1986; Cornette et al., 1987; Banghan, 1988; Hopp, 1989; Rose and Dworkin, 1989). This unit describes the application of hydrophobicity plots to typical problems and provides suggested uses for a few selected scales.

METHODOLOGY

Selecting Hydropathy Scales

The first step in generating a hydropathy profile (or profiles) for an individual amino acid sequence is selecting the appropriate scale(s). Table 2.2.1 lists several widely used scales.

This unit focuses primarily on four hydropathy scales: the Hopp and Woods, the Kyte and Doolittle, the Eisenberg, and the GES scales. Differences among the hydropathy indices for each amino acid in the four scales (Table 2.2.2) arise primarily from differences in the experimental data from which the scales were derived and from the methodologies by which each scale was optimized. The hydrophilicity scale derived by Hopp and Woods is based on solubility values of hydrophobic and hydrophilic amino acids (Nozaki and Tanford, 1971; Levitt, 1976). In the Kyte and Doolittle and the Eisenberg scales, the hydropathy index is a measure of the relative affinity of an amino acid for hydrophobic phases.

The GES scale is based on physicochemical considerations of helical structure and several energetic factors that reflect partitioning of an amino acid side chain between aqueous solution and a membrane bilayer. Both the Kyte and Doolittle and the Eisenberg scales are combinations of earlier scales. The Kyte and Doolittle scale combines values from the water-to-vapor transfers and the internal/external distributions of amino acid residues from known structures as determined by Chothia (1976). The Eisenberg scale is a consensus of the Wolfenden (Wolfenden et al., 1981), Chothia (Chothia, 1976), Janin (Janin, 1979), and von Heijne (von Heijne and Blomberg, 1979) scales and is designed to minimize effects of the outlying values observed for some amino acids in previous scales.

von Heijne and Blomberg	von Heijne and Blomberg, 1979	Theoretical
Roy and Rose	Roy and Rose, 1980	Experimental
Hopp and Woods	Hopp and Woods, 1981	Experimental
Wolfenden	Wolfenden et al., 1981	Experimental
Argos	Argos et al., 1982	Theoretical
Fraga	Fraga, 1982	Theoretical
Kyte and Doolittle	Kyte and Doolittle, 1982	Combination
Fauchere and Pliska	Fauchere and Pliska, 1983	Experimental
Eisenberg	Eisenberg, 1984	Combination
Hopp	Hopp, 1984	Theoretical
Rose	Rose et al., 1985	Theoretical
GES	Engleman et al., 1986	Theoretical
Parker, Guo, and Hodges	Parker et al., 1986	Experimental
Esposti et al.	Esposti et al., 1990	Theoretical

[a]Experimental, largely original data from physicochemical experiments; theoretical, derivation based on analysis of structural data; combination, consensus of multiple scales.

There are several other interesting scales that deserve mention. The first hydropathy scale for membrane proteins was developed and revised by von Heijne (von Heijne and Blomberg, 1979) and corresponds rather closely to the GES scale described above (Engleman et al., 1986). A hydrophilicity scale by Parker, Guo, and Hodges (1986) provides new hydrophilicity values that are determined from HPLC retention times of model synthetic peptides. Another important set of scales includes the statistical scales developed by Argos and co-workers for prediction of membrane-buried helices (Argos et al., 1982; Rao and Argos, 1986). These scales are derived from the statistical preference of specific amino acid residues to form the integral regions in transmembrane proteins, and they have been shown to correlate with highly resolved crystal structures much better than the physicochemical hydropathy scales (Esposti et al., 1990).

Because all hydropathy scales are conceptually similar, the strategy of applying them to a given problem should be analogous regardless of the particular scale chosen. Moreover, although there may always be debates over which of the scales (methods) will prove to be best, experience has shown that application of several different hydropathy schemes and alternative predictive rules will tend to build a consensus picture of protein hydrophobicity.

For this unit the values of the Hopp and Woods and GES scales are multiplied by –1 so that these scales comply with others having peak maxima corresponding to hydrophobicity and peak minima corresponding to hydrophilicity (the scale values were not modified in Table 2.2.2). The Hopp and Woods and GES plots shown are therefore inverse plots.

Applying the Scanning Window Averaging Technique

After the appropriate scale(s) has been selected, the next stage is generating the hydropathy profile for a protein. To create the profile, the numerical values derived from the hydropathy scales for each residue in the protein are repetitively averaged over the length of protein sequence. This procedure is commonly referred to as the scanning window averaging technique (Hopp and Woods, 1981; Kyte and Doolittle, 1982). In practice, the hydropathy is obtained by summing the individual hydropathy values (hydrophobicities or hydrophilicities) for a given number of contiguous amino acids along the protein chain. The sum of

hydropathy values is calculated progressively through the sequence, with each amino acid being the start of a new sum (Fig. 2.2.2). The resultant sums (or averages) are plotted versus the sequence position at the position of the central (or first) amino acid in the segment being summed. The choice of the center versus the first residue has no effect on the calculated profiles but shifts the sequence axis by half the window size. We prefer to plot versus the center position as it seems more intuitive. Similarly, the choice of summing or averaging has no effect on the profile but modifies the relative values plotted on the *y*-axis. We use sums for the profiles presented in this unit. This approach displays the general hydropathic character of a protein.

The ability to discern structurally interpretable features in the calculated hydropathy profile is critically dependent on the width of the scanning window, that is, the number of amino acids included in the summation. Figure 2.2.3 shows the effect of altering the size of the scanning window on hydropathy profiles generated for lysozyme. In Figure 2.2.3A, where the window size is set to 1 amino acid, the resultant hydropathy profile is featureless, providing essentially no structural information. On introducing a window size of 7 amino acids, well-resolved peaks appear in the hydropathy

profile (Fig. 2.2.3B). Increasing the window size to 11 amino acids (Fig. 2.2.3C) results in a smoothing or broadening of observed peaks in the profile, and with window sizes of 15 or 19 amino acids (Fig. 2.2.3D,E), the profiles again have few well-resolved features.

From the family of profiles in Figure 2.2.3, it is readily apparent that window sizes exceeding 10 amino acids result in a loss of local information. This decrease in local information leads to increased errors in predicting hydrophobic regions in globular proteins (Kyte and Doolittle, 1982). In contrast, significant correlations do exist between hydropathy profiles generated with window sizes of 5 to 9 amino acids and known structural elements (Roy and Rose, 1980; Kyte and Doolittle, 1982; Rao and Argos, 1986; Cornette et al., 1987).

In selecting the appropriate window size for a particular problem, the length of the structural property being investigated should be used as a guide. For example, transmembrane helices are roughly 20 residues in length, but the helices of globular proteins tend to be much shorter. One might therefore opt for a larger window size if searching for transmembrane helices, whereas a length of 7 or 9 amino acids is more appropriate for predicting surface sites or secondary structure. In cases of uncertainty, analysis of profiles generated with various window sizes will afford the most reliable results.

Threshold or Cutoff Values

To facilitate the analysis of hydropathy profiles, it is convenient to define a **threshold value**, that is, the amplitude above which the hydropathy value must remain for a particular amino acid to be considered part of a contiguous region. Although somewhat arbitrary, the actual choice of threshold value for a particular profile is often derived empirically or from experience. For example, if one were interested in analyzing the sequences of known membrane proteins for transmembrane helices, then an appropriate threshold value might be one which delineates peaks in the hydropathy profile to approximately 20 amino acids (see section on Predicting Transmembrane Regions in Proteins). As with selecting scanning window size, analyzing profiles with different threshold values should yield more reliable results until experience is gained.

APPLICATIONS

Predicting Interaction Sites

Hydropathy profiles have found widespread use in investigations aimed at elucidating the antigenic structure and surface features of proteins for which there are no three-dimensional structures (Hopp and Woods, 1981; Krystek et al., 1985a,b). Antigenic sites tend to occur on protein surfaces, where predominantly hydrophilic residues are both exposed to solvent and accessible for interaction with antibody. One would therefore anticipate good correlation between antigenic sites and regions of high hydrophilicity. A test of this hypothesis carried out by Tanaka et al. (1985) reported a success rate of 56%.

Figure 2.2.4 depicts the Hopp and Woods profiles for myoglobin generated with a window size of 7 amino acids. Regions of hydrophilicity are detected as peak minima in the profile. The lines at the bottom of Figure 2.2.4 indicate the locations of five major antigenic sites determined experimentally (Atassi, 1984). All of the antigenic sites are associated with regions of high hydrophilicity. In addition, there are two regions of high hydrophilicity (peaks at positions 40 to 45 and 78 to 84) that are not associated with antigenicity. It is plau-

sible that these correspond to antigenic sites that have yet to be identified experimentally, or they may point to an alternate, functionally significant property of myoglobin. Whatever the case, these results serve to emphasize the point that hydropathy profiles should be used only as a guide for predicting antigenicity.

Additional features of protein surfaces can be highlighted by hydropathy profiles. As an example, consider human hemoglobin, whose three-dimensional structure is known (Fermi, 1975). Hemoglobin is found as a tetramer in its native state, being composed of two α- and two β-subunits. In the native protein the β- and α-subunits are folded against one another, forming contact regions that more closely resemble the interior of a globular protein. Because these contact regions are hydrophobic, one might examine hydropathy profiles for regions of hydrophobicity as a means of identifying potential subunit interacting surfaces.

The Hopp and Woods profile for human hemoglobin is shown in Figure 2.2.5. The regions of contact in the β-subunit of human hemoglobin (Yoshioka and Atassi, 1986) are indicated as bars above the profile. The two largest hydrophobic peaks correspond to regions of the β-subunit in contact with each of the α-subunits. Analogous analysis of hydropathy profiles has been successfully used to identify the subunit interacting surfaces for the α-subunits of glycoprotein hormones lutropin and follitropin (Krystek et al., 1991, 1992).

Human hemoglobin also provides a demonstration of the dangers of using hydropathy profiles for analyzing antigenic sites of proteins that possess significant quaternary structure. In Figure 2.2.5 the lines below the profile indicate the regions of five major continuous antigenic determinants. Although two sites correlate with regions of hydrophilicity, the others do not. In such cases the amino acid sequence alone is not sufficient for predictability. This may be due in part to the unique nature of proteins composed of multiple subunits.

Correlating Profiles with Secondary Structure

An increasingly important application of hydropathy profiles is their use in conjunction with secondary structure prediction tools (see *UNIT 2.3*). Figure 2.2.6 shows the hydropathy profiles for interleukin 1β (IL-1β) generated with the Eisenberg scale (Fig. 2.2.6A) and the Kyte and Doolittle scale (Fig. 2.2.6B), using a scan window of 7 amino acids. The solid bars

above the profiles indicate the locations of β strands found in the crystal structure of this all-β protein (Finzel et al., 1989). Although there is a difference in scale magnitude between the Kyte and Doolittle and Eisenberg methods, both profiles show exceptionally good correlation of hydrophobicity (peak maxima) with the location of β strands. The correlation of hydrophobicity with β-sheet structural elements is a direct reflection of the fact that sheets are most often located in the hydrophobic interior of a protein; thus, they comprise residues most compatible with the hydrophobic environment. There is also good correlation between hydrophilicity (peak minima) and the location of turns in proteins. For interleukin 1β essentially all of the turns identified in the structure correspond to minima.

Figure 2.2.7 shows the hydropathy profiles for myoglobin, a protein composed solely of α helices. The larger α helices appear to correlate with peak maxima. Like β sheets, helices are frequently found in regions of hydrophobicity in the hydrophobic core of proteins. Because of the interspersed nature of hydrophilic and hydrophobic residues of amphipathic helices, however, hydropathy profiles are less useful in predicting the location of these helices. Moreover, as both helices and sheets result in peak maxima, the hydropathy profile is not sufficient to discriminate between them. Therefore, correlations of secondary structure with protein hydropathic character are most successful when used in conjunction with protein secondary structure prediction algorithms (see *UNIT 2.3*).

Predicting Transmembrane Regions in Proteins

Perhaps the most popular use of hydropathy profiles is predicting transmembrane regions in proteins. In addition to hydropathy scales, there are several membrane preference scales. Such scales have been developed independently from the hydropathy scales and are based on statistical distributions of each amino acid in membrane regions of proteins. The statistical scales have been previously compared to the hydropathy scales (Esposti et al., 1990); in general, they are equally efficient at predicting the location of the transmembrane and amphipathic helices.

Examining the structure of known membrane proteins has enabled the predictive rules

for the various scales to be optimized. In addition, estimates of the hydrophobic thickness of the bilayer have provided guides to the minimum number of helical amino acids necessary to span the bilayer: the minimum number is estimated to be 20 (Engleman et al., 1986). This greatly facilitates the prediction of putative transmembrane helices by adding an additional criterion to the analysis of hydropathy profiles for transmembrane regions, namely, maxima in the profiles must span ~20 residues.

Figure 2.2.8A shows the Kyte and Doolittle profile for bacteriorhodopsin, a membrane protein whose structure is known (Henderson et al., 1990). For Kyte and Doolittle profiles, the best resolution is seen for window scans of 7 or 9 amino acids and threshold values of 0.7 × window size. For a window scan of 7, the threshold value is 4.9. There are seven major peaks with threshold values greater than 4.9 that span at least 20 amino acids (indicated by brackets above the profile in Fig. 2.2.8A). Comparison of the predicted transmembrane regions with the location of the actual helices identified in the structure (bars above the profile) indicates that the prediction is quite good. Similar agreement is seen when the method of Engleman et al. (1986) is used to predict the transmembrane regions for bacteriorhodopsin (Fig. 2.2.8B).

Although the location of the helices can be predicted reliably, neither the Kyte and Doolittle nor the GES method is able to predict accurately the boundaries of the transmembrane regions. Fortunately, visual inspection of the sequence, as well as general features of the

BOULDER CENTRAL UNIVERSITY LIBRARY

transmembrane helices, can frequently be used to delineate transmembrane regions and the interfacial residues at each end of the helices. Some general features common to transmembrane regions to consider are as follows. (1) Approximately 75% of the amino acids in transmembrane regions are hydrophobic (Leu, Ile, Val, Met, Phe, Trp, Tyr, Cys, Ala, Pro, and Gly). (2) Proline residues are found in ~20% of the transmembrane helices but in only 3% of globular proteins (Barlow and Thornton, 1988). (3) Aromatic residues are clustered near the interface of the transmembrane helix and bulk water.

Positional preferences for amino acids in transmembrane regions have been identified for single-spanning membrane proteins (Landolt-Marticorena et al., 1993) and can serve as a further guide for delineating the ends of transmembrane regions. It can be expected that these preferences will be similar for polytopic membrane proteins. The positional preferences define a motif with the following characteristics: an extracellular terminal flanking region (Asp, Ser and Pro); an extracellular-interfacial region (Trp); a transmembrane domain composed primarily of hydrophobic residues (Leu, Ile, Val, Met, Phe, Trp, Cys, Ala, Pro, and Gly); an intracellular-interfacial region (Tyr, Trp, and Phe); and an intracellular terminal flanking region (Lys and Arg). Application of these sequence analysis rules for transmembrane proteins greatly improves the results of using hydropathy profiles for predicting transmembrane regions.

CONCLUSIONS

1. Virtually all hydropathy scales are able to reveal structural information in an equivalent manner. Selection of the appropriate hydropathy scale is therefore a practical and/or personal decision.

2. Window scanning procedures should use an appropriate window size for the structural element being examined: 7 or 9 amino acids for predicting surface sites or secondary structure and 19 amino acids for predicting membrane-spanning regions.

3. Identification of interaction sites can be accomplished using peak minima (hydrophilicity).

4. Correlation of protein secondary structure with hydropathy profiles may be useful for protein structure prediction methodology (see *UNIT 2.3*).

RUTGERS UNIVERSITY LIBRARY

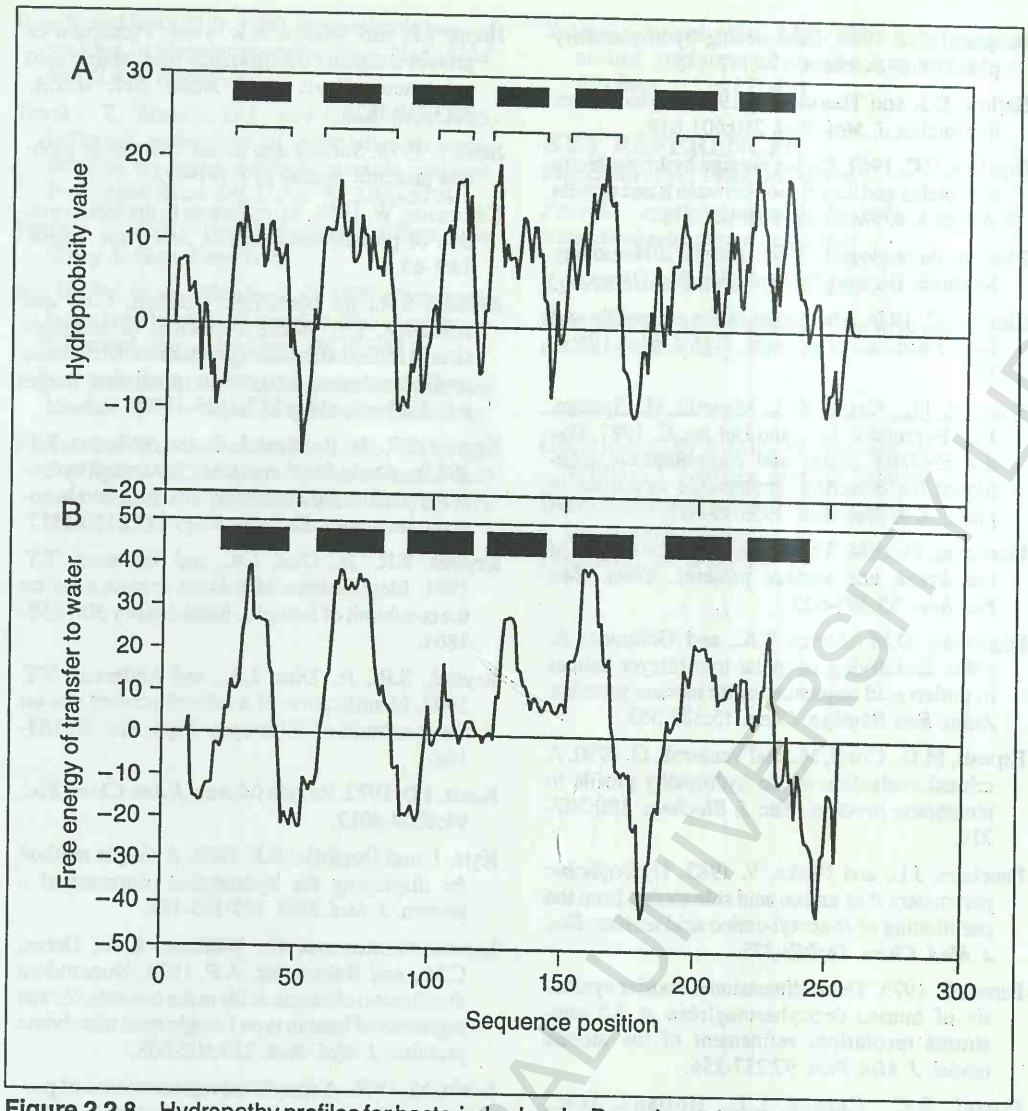

Figure 2.2.8 Hydropathy profiles for bacteriorhodopsin. Bars above the profiles mark the locations of the helices. (**A**) Kyte and Doolittle profile generated using a scanning window size of 7 amino acids. Brackets indicate the helices predicted on the basis of the profile alone. (**B**) GES profile generated using a scanning window size of 19 amino acids.

5. Prediction of transmembrane regions of integral membrane proteins can be made using a variety of scales and protocols; analysis of the hydropathy profiles should be augmented with the applicable sequence analysis rules.

ACCESSIBILITY OF SOFTWARE

Most commercial personal computer or computational packages (Genetics Computer Group, 1994; Biosym Technologies, 1991; Tripos Associates, 1993) contain algorithms for hydropathy profile generation along with other secondary structure prediction tools (see Table 2.3.6). In addition, the authors of each scale or protocol have published analysis programs (Table 2.2.1), of which many are available from public domain sources on the Internet. Algorithms can also easily be encoded into programming languages or spreadsheets and interfaced with numerous graphical software packages for plotting the hydropathy profiles (if graphics are not included in the particular prediction program). These are also discussed in *UNIT 2.1*.

Protein Secondary Structure Prediction

It is widely accepted that knowledge of the structure of a protein can provide important information regarding its function and mechanism of action. However, determining the three-dimensional structure of a protein, whether by X-ray crystallography (Wyckoff et al., 1985; Blundell and Johnson, 1976) or nuclear magnetic resonance (NMR) spectroscopy (Oppenheimer and James, 1989; Wuthrich, 1986), remains a formidable task, as it requires relatively large amounts of pure protein (generally greater than milligram quantities). Thus, the structures of many proteins will remain out of reach. At the same time, continual advances in molecular biology provide protein sequence information (primary structures) at a pace that far exceeds the speed with which higher-order protein structures can be determined, thus making the need for methods to derive structural information even more pressing. This unit describes procedures developed for predicting protein structure from the amino acid sequence.

On the basis of function and location in the cell, proteins can be loosely divided into three groups: globular, structural, and membrane. To date, the majority of protein structural data has been derived from studies of globular (soluble) proteins because of the ease of chemical handling of globular proteins. Thus, a wide disparity has developed in the number of three-dimensional structures that have been experimentally determined in the three protein groups. As a result, current secondary structure prediction schemes apply almost solely to globular proteins.

In the native structures of globular proteins, the hydrophobic residues are generally buried in the interior and the hydrophilic residues are exposed to the surrounding solvent (Kauzmann, 1959; Fisher, 1964; Dill, 1990). Disulfide bonds are often present and stabilize the structure. Sections of amino acid sequence rich in hydrophobic residues can be correlated with secondary structural elements such as α helices and β strands (Roy and Rose, 1980). Those rich in polar residues correspond to surface loops and β turns (Kuntz, 1972; *UNIT 2.2*). These secondary structural elements (Pauling and Corey, 1951; Pauling et al., 1951) are characterized by hydrogen bonding between the amino and carboxyl groups of the polypeptide backbone (Schulz and Schirmer, 1979).

Several reviews of protein structure exist, and readers are referred to books by Schulz and Schirmer (1979) and Branden and Tooze (1991) for thorough discussions of protein structure. Protein secondary structure elements associate to form compact domains. Levitt and Chothia (1976) and Richardson (1981) have classified protein domains according to the types of arrangements of secondary structures that form them. Illustrations for the four classes, referred to as all-α, all-β, α/β, and α+β, are available (Richardson, 1981; Lesk, 1991). This unit focuses on examining secondary structure predictions using specific examples from different protein classes; methods of predicting folding class are also discussed.

This unit is divided into four sections. The first section is an overview and brief history of structure prediction schemes. The second section describes four distinct prediction schemes, with emphasis on their differences. In the third part each prediction scheme is used to evaluate three proteins that have different folding patterns. The final section is a comparison of the prediction results and suggestions for secondary structure prediction.

OVERVIEW OF PREDICTION SCHEMES

Early Predictive Schemes

Two of the earliest secondary structure prediction methods were developed by Guzzo (1965) and Prothero (1966). By analyzing a database of protein structures and corresponding sequences, they generated a set of rules for predicting structure. Because of the limited number of structures available at the time, their prediction methods were restricted to helices, the most abundant conformation in the structures available.

Soon after, Schiffer and Edmunson (1967) developed the helical wheel method, a pictorial tool that is still widely used. The helical wheel is a circular plot that represents the view one obtains when looking down the helix axis (Fig. 2.3.1). The "spokes" of the wheel are precisely positioned on the basis of the Corey-Pauling α-helical geometry, having 3.6 residues per turn, which results in an angular shift of two neighboring residues of 100° (Pauling et al., 1951). A helical wheel is constructed by placing successive amino acids at the spokes of the wheel.

Helical wheels have been particularly valuable for identifying proteins and peptides that contain amphipathic helices. In an amphipathic

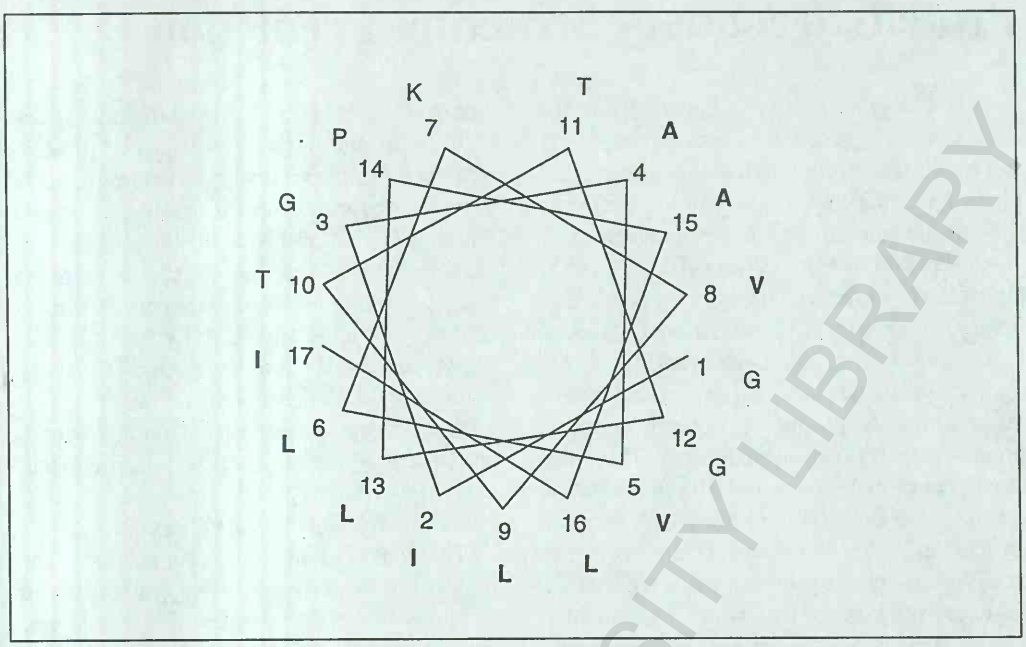

Figure 2.3.1 Helical wheel for a portion of the amphipathic helix of melittin. Residues in bold type form a hydrophobic side. Note that this is not a perfect amphipathic helix as the polar face includes Ala-4, Ala-15, and Val-8. This helix also contains several glycine residues, which are not commonly found in helices (Table 2.3.1).

helix, hydrophobic residues will cluster to one side of the wheel and polar residues will be found on the opposite side. Figure 2.3.1 shows a helical wheel for the amphipathic helix of melittin. Helical wheels have often been used for analyzing helical dimerization proteins such as leucine zippers (Krystek et al., 1991; O'Shea et al., 1992), for designing helical multimers (Harbury et al., 1993; Kamtekar et al., 1993; Lovejoy et al., 1993), and for predicting and analyzing membrane proteins which contain helices that span the lipid bilayer (Baldwin, 1993).

Other early predictive schemes include those developed by Dunhill (1968) and Lim (1974). Dunhill's "helical net" is a pictorial method that is similar to the helical wheel and is still used in protein design and helix prediction (DeGrado, 1988; Goodman and Kim, 1991). Lim's method relies on an extensive set of rules derived from the physicochemical properties of amino acids in conjunction with the analysis of a structural database. The large number of detailed rules, however, makes the Lim method unwieldy. When several methods were compared in a blind test organized by Schulz et al. (1974), the methods of Ptitsyn and Finkelstein (1970) and Chou and Fasman (1974a,b) performed better than others (Burgess et al., 1971; Lewis et al., 1971; Robson and Pain, 1971; Nagano, 1973).

Statistical Prediction Schemes

The statistical methods developed by Chou and Fasman (1974a,b) and by Garnier et al. (1978) are the most prominent of the class of predictive schemes based on statistical amino acid preference rules. These secondary structure prediction schemes tacitly assume that only local sequence interactions influence the formation of local structure. This is almost certainly an oversimplification. Significant interactions occur between protein secondary structural elements (tertiary structure); these interactions may involve hydrophobic and/or electrostatic interactions between structural units. Therefore, the success and accuracy of prediction schemes that rely on empirical algorithms are necessarily limited and are unlikely to exceed a level of 70% to 75%. Reports of secondary structure prediction accuracy levels of ~70%, however, are not uncommon using these methods (Fasman, 1985).

Other Predictive Schemes

Two additional methodologies for structure prediction not based on statistics of amino acid occurrence have evolved. Of the neural network methods (Quinn and Sejnowski, 1988; Rost and Sander, 1993a,b; Kneller et al., 1990), that of Rost and Sander claims a level of predictive accuracy exceeding 70% for all proteins tested and is publicly available through the

RCU IASTATE UNIVERSITY LIBRARY

Internet computer network (for details, see discussion of Applying the PHD Scheme and Table 2.3.6 therein). The method of Stultz et al. (1993) is based on state-space modeling with a set of predefined structural class models.

Selecting Prediction Tools

Secondary structure prediction proceeds as follows. First, it should be confirmed that the three-dimensional structure has not yet been determined. This can be done by searching known X-ray and NMR structures in the Protein Data Bank (Brookhaven, 1994) for an amino acid sequence identical to that of interest. Next, identification of proteins with significantly similar sequences whose structures are already known should be attempted. Numerous software packages are available for performing similarity searches (see *UNIT 2.1*). If proteins of similar sequence (>20% identity) are found, the Protein Data Bank should again be searched to determine whether the structures of any of those proteins are known. If so, then comparative homology modeling (Greer, 1990; Bajorath et al., 1993) can be used to develop a three-dimensional model of the desired sequence. Only if there are no proteins in the structural database of sufficient similarity should protein secondary prediction schemes be used. It should be pointed out, however, that proteins may have the same fold without a detectable sequence similarity (Kabsch and Sander, 1984, 1985). In the future, sequence threading through known three-dimensional structures will be helpful (Jones et al., 1992; Sippl and Weitckus, 1992).

It is recommended that protein secondary structure prediction be performed in conjunction with other sequence analysis approaches, such as hydrophobicity profiling, flexibility analysis, surface exposure experiments, charge distribution mapping, and motif searches (*UNIT 2.2*; Fasman, 1989b; Genetics Computer Group, 1994). For investigators using methods to predict protein secondary structure, at least two questions should be addressed: (1) which predictive scheme(s) should be used, and (2) what are the advantages of one method over others? This unit attempts to find answers to these questions by studying three proteins in detail: human hemoglobin β-subunit, human interleukin 1β (IL-1β), and human profilin I (see Application of Secondary Prediction Methods and Fig 2.3.2).

METHODS FOR SECONDARY STRUCTURE PREDICTION

The Chou and Fasman Method

The most popular secondary structure prediction scheme is the statistical method of Chou and Fasman (1974a). Using a database of 15 protein structures determined by X-ray crystallography, Chou and Fasman tabulated the number of occurrences of a given amino acid in α helix, β strand, or coil. From the tabulation, a set of conformational preference parameters for each amino acid type was calculated. The preference parameters were based on three functions: (1) the relative frequency of a specific amino acid type within each protein, (2) the occurrence of that amino acid in a given type of secondary structure, and (3) the fraction of amino acid residues occurring in each type of secondary structure. With the conformational preference parameters in hand, the authors then derived a set of empirical rules for predicting protein secondary structure (Chou and Fasman, 1974b).

Chou and Fasman later published an extension of their analysis using a larger set of X-ray structures, totaling 29 proteins and over 4700 amino acids. In addition to refining the values for α helices and β strands, they included a conformational preference parameter for β turns as well (Chou and Fasman, 1977, 1978a,b). For β turns, a positional preference for residues was identified; for example, proline was found to occur more frequently in position 2 of the turn than in positions 1, 3, or 4.

A further refined set of conformational preference parameters for helical and sheet residues was later derived from an expanded data set of 64 protein structures (Chou, 1989). These parameters are similar to those based on the 29 protein structures (differences are noted in Chou, 1989). An interesting addition to secondary structure prediction using the conformational preference parameters is the prediction of protein class. Chou presented a computerized algorithm that assigns a structural class to proteins on the basis of amino acid composition; however, these predictions have not been widely used.

In the initial studies, Chou and Fasman used the conformational preference parameters to describe amino acids as being formers, breakers, or indifferent for helical and strand regions (Chou and Fasman, 1974a). Their analysis showed that residues with the highest prefer-

Below the amino acid sequence are given the turn prediction (T), the α helix (thin line) and β strand prediction (thick line), the location of positive (upward spikes) or negative charges (downward spikes) as derived specifically from amino acid side chains, and a hydrophobicity profile (HB).

ence for helices resided near the helix center, whereas residues with low helix preference could be found clustered at the helix termini. For helix and strand, residues were independently classified as strong formers, formers, weak formers, indifferent, breakers, and strong breakers. Table 2.3.1 contains a list of the conformational preference parameters and refined conformational assignments derived from the analysis of 64 proteins (Chou, 1989). These values are combined with the turn preferences shown in Table 2.3.2, or values from the 29-protein study (Chou and Fasman, 1978a,b; Prevelige and Fasman, 1989), to carry out sequence prediction as described below.

An important contribution to helix prediction strategies is the recognition that helix start and stop signals in the amino acid sequence grammar are quite distinct (Presta and Rose, 1988; Richardson and Richardson, 1988). The

α-helical structures in proteins are commonly stabilized by reciprocal hydrogen bond formation between the unpaired main-chain amino and carboxyl groups near the helix termini and the side chains of amino acids flanking the termini (Harper and Rose, 1993). The helix-terminal residues are referred to as the N-cap and C-cap. Because of the unique geometry of proline, this amino acid is frequently found at the N-cap + 1 position and has been referred to as being an α-helix initiator (Richardson and Richardson, 1988). Residues that typically occupy the N-cap and C-cap positions of helices are listed in Table 2.3.3.

The Garnier, Osguthorpe, and Robson Method

The Garnier, Osguthorpe, and Robson (GOR) method (Garnier et al., 1978; Garnier and Robson, 1989) is a widely available secondary structure prediction method that has been incorporated into several computer packages, such as that from Genetics Computer Group (GCG). Although the GOR method incorporates essentially all the elements of the Chou-Fasman statistics, it also uses information theory to reach the final decision. A detailed description of the GOR method can be found elsewhere (Garnier and Robson, 1989).

In principle, the GOR method assigns the conformation of a given residue by considering the contribution of residues relatively distant to it in the sequence. On the basis of studies showing the interdependence of residue conformations up to eight amino acids away, the GOR method assigns single-residue information values to each amino acid along the polypeptide chain. The predicted conformational state for an amino acid is the state with the highest positive information value. An extension of this procedure, the GORIII method, has been developed to use pair information instead of directional information. The GORIII method extracts both single-residue information values

and pair information values for each possible pair and for amino acids within eight amino acids of a central residue. The predictive accuracy of the GOR methods is similar to that of the Chou and Fasman method (Garnier et al., 1978). Thus, the GOR methods may serve as a check of the results obtained with the Chou and Fasman method.

The EMBL Profile Neural Network Method

An important feature of the EMBL Profile Neural Network (PHD) prediction scheme is the use of multiple sequence alignments (Rost and Sander, 1993a,b). Previous studies have shown that homologous proteins (generally with at least 20% to 30% sequence identity but often less) frequently have identical three-dimensional folds (tertiary structure). Thus, multiple sequence alignments are grouped by structural family and used as input. By considering many aligned sequences, the algorithm makes use of more information about structure than is available from just the individual protein sequence for which the secondary structure is to be predicted.

To determine which protein sequences are to be used in the prediction, the PHD method uses a weighted dynamic programming method, MaxHom (Sander and Schneider, 1991), in searching a database of sequences. A family profile for the input sequence is generated and the amino acid frequencies at each alignment position are calculated for use in the prediction. Results have shown that the multiple sequence alignments improve secondary structure prediction >6% compared to single-sequence predictions (Rost and Sander, 1993a,b).

The PHD method uses a **reference network** or **neural network** that has been trained and tested on a database of nonhomologous protein structures. In a typical database there is an uneven distribution of secondary structure types, such that there are many more examples of turns than of helices or sheets (Rost and Sander, 1993a,b). Because of the uneven distribution, empirically based predictions of loops are more accurate than those of helices, which in turn are more accurate than those of sheets. The neural network approach of the PHD method eliminates this bias: Rost and Sander developed a network that is trained with each type of secondary structure in equal proportion, rather than the proportions present in any database of protein structures. This results in a more balanced prediction.

The network system for structure prediction consists of three layers. In the first layer, secondary structure is predicted on the basis of the multiple aligned sequences. The results are passed to the second layer, which collectively considers secondary structure elements that are adjacent in the protein sequence, thereby allowing nearest neighbor structure to influence the structure of a particular region of the protein. The third layer of the network averages the results of the independently trained networks. The output from the third layer is determined by a "winner take all" prediction of the secondary structure at a given sequence position (Rost and Sander, 1993a,b).

The PSA Method

The Protein Sequence Analysis (PSA) method (Stultz et al., 1993) computes the probability that a given amino acid belongs to a particular secondary structure element when there are no homologous protein sequences or structural data. To do this, mathematical models were developed for 15 single-domain protein **superclasses** or **macroclasses**. These superclasses, patterned after the protein class categorization of Richardson (1981), are groups of proteins with similar secondary and tertiary structures. The mathematical models represent constraints on the patterns of secondary structure elements for a given protein class.

To perform structure prediction, the PSA method uses the amino acid sequence to calculate the probability that a given residue is contained in each of the modeled secondary structure elements. Also calculated is the probability that the submitted sequence is a member of one of the predefined superclasses. Thus, in addition to evaluating the secondary structure prediction, the PSA method provides the bonus of the potential tertiary structural information contained in the predicted structural superclass.

The Helical Wheel

The helical wheel is a plot of the amino acid residues around a potentially helical segment (see Fig. 2.3.1 and discussion in Early Predictive Schemes). The method was developed to find helices with a hydrophobic face buried away from a polar solvent, with the graphical representation showing the clustering of polar and/or nonpolar residues toward one face of a helix. In its original use the helical wheel facilitated the identification of potential helical segments in protein sequences (Schiffer and Edmundson, 1967), but its applicability has since been expanded to include designing proteins (e.g., leu-

BOSTON UNIVERSITY LIBRARY

cine zipper proteins; Harbury et al., 1993; Kamtekar et al., 1993; Lovejoy et al., 1993) and studying transmembrane proteins (e.g., G-protein-coupled receptors; Baldwin, 1993).

APPLICATION OF SECONDARY STRUCTURE PREDICTION METHODS

Applying the Chou and Fasman Method

The wide use of the Chou and Fasman method is due in part to the simplicity of application, ease of understanding, and potential interactive nature of the analysis. It also ranks favorably in accuracy of prediction relative to other methods. Application of the method entails the following steps.

1. Conformational preference parameters for each type of secondary structure are locally smoothed by averaging techniques (see *UNIT 2.2* for an example of the scanning window averaging method) in order to calculate α-helix, β-sheet, and turn probabilities along the polypeptide backbone.

2. The α-helix, β-strand, and turn probabilities are plotted versus sequence position for interpretation. Basically, the conformation is assigned according to the highest curve (Fig. 2.3.2, Fig. 2.3.3, and Fig. 2.3.4).

3. On the basis of conformational preference parameters, amino acids are assigned as formers, breakers, or indifferent for α-helical and β-sheet regions (Fig. 2.3.3A).

4. Program options usually include full predictions that are based on the original Chou and Fasman rules (Table 2.3.4). Predictions can also be made by the user in an interactive environment by combining the Chou and Fasman rules with sequence analysis using other empirical methods such as hydrophobicity profiling, flexibility prediction, charged residue mapping, and surface probability calculation (Fig. 2.3.3 and Fig. 2.3.4; see also Comparison of Prediction Schemes). We find that an interactive approach allows for the best interpretation of the prediction results (Fasman, 1989a; Schulz, 1988). Several other correlations can be used in this analysis and are listed in Table 2.3.5. Many programs can also generate sketches of predicted peptide structures (Fig. 2.3.5).

Applying the GOR Scheme

The GOR scheme is coded into many commercial and academic protein structure analysis packages. This method provides estimated probabilities that a given residue is in a particular conformational state, and it predicts the conformation of an amino acid without any input from the user other than the sequence of interest. There are two outputs from the GOR method. The first is a plot of the turns, α helices, and β strands as predicted from the method. The second is a summary of the full protein structure prediction similar to that produced by the Chou and Fasman method. Unlike the Chou and Fasman method, assignment of each amino acid to a structural element is made automatically. Because many prediction schemes can be printed in the same output format, it is possible to print results of Chou and Fasman, GOR, and other structural predictions together for a more interactive analysis of the sequence (Fig. 2.3.4). Use of a combination of structural prediction schemes and the secondary structure correlations presented in Table 2.3.5 should increase the accuracy of secondary structure prediction.

Applying the PHD Scheme

Access to the PHD scheme is available only through electronic mail or the WWW (World Wide Web). The Internet address for this service is given in Table 2.3.6. To perform sequence analysis with the PHD scheme, one merely needs to supply the sequence to the EMBL Predictprotein server. Additionally, one can submit prealigned sequences or a defined set of homolog sequences to be used in the predictive scheme. If a single sequence is submitted, the scheme will search the sequence database, and, if homologs are found, the sequence prediction will be performed on the multiple sequence alignments (Fig. 2.3.6). The output from the scheme consists of several pages describing the network and analysis, including the list of any homologous proteins along with the sequence alignment used in the analysis, the definition of accessibility, and a reliability index for the accuracy of prediction (Fig. 2.3.7). This method provides prediction of solvent accessibility as well as secondary structure. A comparison of this analysis to others described in this unit is described in the section on Comparison of Prediction Schemes.

Applying the PSA Scheme

The PSA scheme, like the PHD scheme, has been established on the Internet (Table 2.3.6). The electronic mail server, called Protein Sequence Analysis (PSA) System, accepts as input the amino acid sequence of a protein. After sequence analysis the server returns four

Figure 2.3.4 Secondary structure prediction for human profilin I using the methods of Chou and Fasman and GOR as implemented by GCG: PeptideStructure algorithm and plotted using PlotStructure utility. **(A)** Predicted secondary structure and **(B)** numerical output for residues 1 through 35.

BCU IASI/CENTRAL UNIVERSITY LIBRARY

with the Chou and Fasman, GOR, PHD, and PSA methods (Fig. 2.3.9). Analysis of the Chou and Fasman profiles was enhanced by displaying smoothed hydrophobicity profiles and consulting the amino acid positional preferences of Table 2.3.3. An example of the complete analysis of profilin is presented in Figure 2.3.3, Figure 2.3.4, and Figure 2.3.5 (or Fig. 2.3.2C). The GOR predictions were made with the GCG commercial package (Fig. 2.3.4). The PHD and PSA predictions were obtained from the electronic mail response to a structure query; ex-

Table 2.3.4 Abbreviated Chou and Fasman Prediction Rules[a]

Feature	Rule
Helix	Helix is initiated by a cluster of four helix-promoting residues out of six amino acids along the polypeptide sequence. Helical segment is extended in both directions until sets of tetrapeptide breakers are reached. Prolines can occur only within the first three residues of the N-terminal end. A segment length of six or more amino acids with α probability greater than β probability is predicted as helical.
Strand	A cluster of three β formers or a cluster of three β formers out of five amino acids along the polypeptide sequence will initiate β-strand formation. The β strand is extended in both directions until terminated by a set of tetrapeptide breakers. A segment of three or more amino acids with β probability greater than α probability is predicted as β strand.
Turns	Turn probability is calculated as peaks of probability that are greater than α or β probability. The β turns are also identified by $Pt > 0.75 \times 10^{-4}$, where $Pt = f_i \times f_{i+1} \times f_{i+2} \times f_{i+3}$.
Overlap	For a region containing overlapping α helix and β strand, the prediction would be for helix if the α probabilities are greater than β probabilities, and strand if β probabilities exceed α probabilities.

[a]For the complete set of prediction rules, see Chou and Fasman (1974a,b, 1978a,b).

Table 2.3.5 Secondary Structure Correlations

Structure	Characteristics
β strands	Often correspond to peaks of hydrophobicity β-branched amino acids (Val, Ile, Thr) are typical Positively charged residues are relatively abundant Negatively charged residues (Glu) virtually never occur Average residue length is 7, resulting in short and acute peaks in hydrophobicity plots (see *UNIT 5.2*) β bulges may occur in the edge strands. Their signature is small amino acids and glycines (e.g., Gly-Xxx-Gly sequence in immunoglobulin V fold, strand G).
α helices	Hydrophobicity peaks are longer, with a fine structure (teeth). Ideally, fine structure shows $n + 4$ periodicity. Glu, Ala, Leu, are typical Amino acid preferences exist at the N-cap and C-cap positions (see Table 2.3.3) Prolines can occur in the first turn of helices in globular proteins, and most frequently occupy the N-cap + 1 position Prolines, which "kink" the helices, are overrepresented in transmembrane helices Glycines frequently occur at the C-cap position Hydrophobic residues often occupy positions N-cap + 4 and C-cap − 4 Helices may be completely buried and not amphipathic

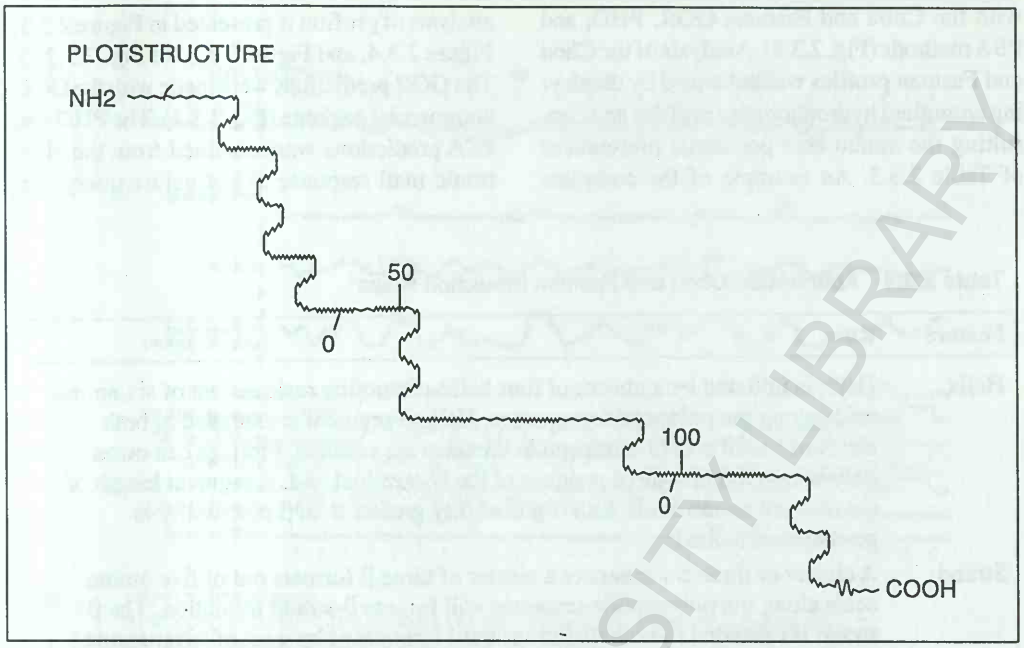

Figure 2.3.5 Sketch of the human profilin secondary structure as predicted in Figure 2.3.3 and Figure 2.3.4 by Chou-Fasman method.

amples of the output for the profilin secondary structure prediction are provided in Figure 2.3.6, Figure 2.3.7, and Figure 2.3.8.

Figure 2.3.9A summarizes the results of secondary structure prediction for the β subunit of human hemoglobin. Immediately below the amino acid sequence is the location of the eight helices found in the three-dimensional structure of hemoglobin (Brookhaven Protein Data Bank entry 2hhb; Fermi, 1975). The Chou and Fasman scheme predicts most of the helical residues in helices 1, 2, 3, 4, 6, 7, and 8. Helices 6 and 7 are predicted to be longer than they actually are, and helices 2 and 3 are not distinguished as independent helices. A turn is predicted in place of the fifth helix. The GOR method predicts most of the residues for helices 1, 2, 5, 6, and 8, but it predicts a turn for helix 3 as well as a turn and a strand for helix 7. The PHD program found over 400 sequence homologs of hemoglobin-β, with one of the sequences being the submitted sequence. The PHD prediction identified a homolog with a known three-dimensional structure in the protein database and also suggested structure prediction by homology modeling. The prediction by PHD did quite well, accounting for seven of the eight helices and missing only the small helix 4. The PSA procedure suggested the α/β class as the most probable. Most of the helical residues in helices 2, 3, 5, 6, and 8 and part of helix 7 were correctly predicted. Helix 1 was missed by the PSA method, however, and the C- and N-terminal residues of helices 2 and 3, respectively, were predicted to be in sheet structure.

Figure 2.3.9B summarizes the results of secondary structure prediction for interleukin 1β. IL-1β contains 12 β strands connected by intervening turns (Brookhaven Protein Data Bank entry 1i1b; Finzel et al., 1989). The Chou and Fasman method predicted most of the residues in 8 of the 12 strands in the β sheet (strands 1, 2, 4, 5, 6, 8, 11, and 12). Helical regions were predicted for β strands 3 (with the adjacent turn) and 7. The Chou and Fasman method correctly predicted several of the turns. The GOR method correctly predicted 4 of the 12 β strands, but it predicted helical regions for β strands 3 (with the adjacent turn), 5, 6, and 8. Interestingly, both the Chou and Fasman and GOR methods predict helix for the third strand. This may be due to the negatively charged glutamate, which is generally considered a strand breaker (see Table 2.3.1). For IL-1β, the PHD output listed the 10 sequence homologs that were used in the structure prediction and also identified a known three-dimensional structure in the protein database. The PHD method correctly predicted most of the residues in the 12 β strands; however, a deficiency in the method is that it does not predict the location of possible turns. The PSA method did not successfully predict either the class or the secondary structure of IL-1β: the method pre-

dicted the protein fold class to be all-α rather than all-β, and therefore incorrectly predicted α structure rather than β structure. It is noteworthy that several of the predicted α helices correspond to the location of β strands, namely, those of β strands 2, 3, 4, 5, 7, 9, 11, and 12. Further testing is required to determine whether there are any inherent problems with the predictions of all-β proteins by the PSA method.

Figure 2.3.9C summarizes the results of secondary structure prediction for human profilin, an α/β protein whose high-resolution structure (Metzler et al., 1993, 1995) was not publicly known at the time of testing. Profilin is composed of a central seven-stranded, antiparallel β sheet and four helices (Fig. 2.3.10). Seven turns that connect the helical and sheet structural elements in the structure have been identified. Figure 2.3.2C, Figure 2.3.3A, and 2.3.4A show typical Chou and Fasman profiles as determined with the programs of Novotny (Novotny and Auffray, 1984), PepPlot (GCG, 1994), and Plotstructure (GCG, 1994). Figure 2.3.3B shows the numerical output from the modified Chou and Fasman prediction programs (PepPlot), and Figure 2.3.4B shows the automated prediction by the Peptidestructure program using the Chou and Fasman and the GOR methods. A schematic representation of the predicted protein secondary structure is shown in Figure 2.3.5.

The Chou and Fasman method predicted six of the seven β strands and the two terminal helices of profilin (Fig. 2.3.8C). This method also predicted correct locations of several of the turns located between the strands. In comparison, the GOR method performed significantly worse, predicting only four of seven β strands and neither of the terminal helices. The PHD method identified six sequence homologs of profilin (Fig. 2.3.6) that it used in the secondary structure prediction (Fig. 2.3.6). The method correctly predicted all seven β strands and the two terminal helices. It did, however, predict additional β strands for the interior helices but did not predict the locations of any turns (owing to a deficiency in the method, as stated previously). The PSA method predicted the profilin sequence to be a member of the all-β protein fold class (Fig. 2.3.8). The method

Figure 2.3.6 Sequence homologs and a portion of the sequence alignment statistics used in secondary structure prediction for human profilin I with PHD, the EMBL neural network method. Secondary structure prediction given in Figure 2.3.7. For description of column labels see Rost and Sander (1993a,b) and EMBL Predictprotein Server (address given in Table 2.3.6).

did correctly predict the location of five of the β strands, but it predicted additional β strands for the amino and carboxyl termini and the second interior helices. The PSA method correctly predicted several of the turns located between the β strands, as well.

In summary, both the PHD and the interactive Chou and Fasman method performed well, correctly predicting most secondary structural elements (see Table 2.3.7). The interactive Chou and Fasman method generally outperformed the GOR method. However, it must be pointed out that in predicting the secondary structure with the Chou and Fasman method, the correlations contained in Table 2.3.3 and Table 2.3.5 and the Chou and Fasman rules contained in Table 2.3.4 facilitated both locating helix ends and discriminating between helix and strand when ambiguity existed. In contrast, a strict interpretation of the GOR results was used. It is also possible to interpret the GOR results interactively; this may equalize the predictive power of the two methods.

In testing the PHD method, we were unable

Figure 2.3.7 Secondary structure prediction for human profilin I with PHD, the EMBL neural network method. Sequence homologs and a portion of the sequence alignment used in the analysis are given in Figure 2.3.6.

DUKE UNIVERSITY MEDICAL CENTER LIBRARY

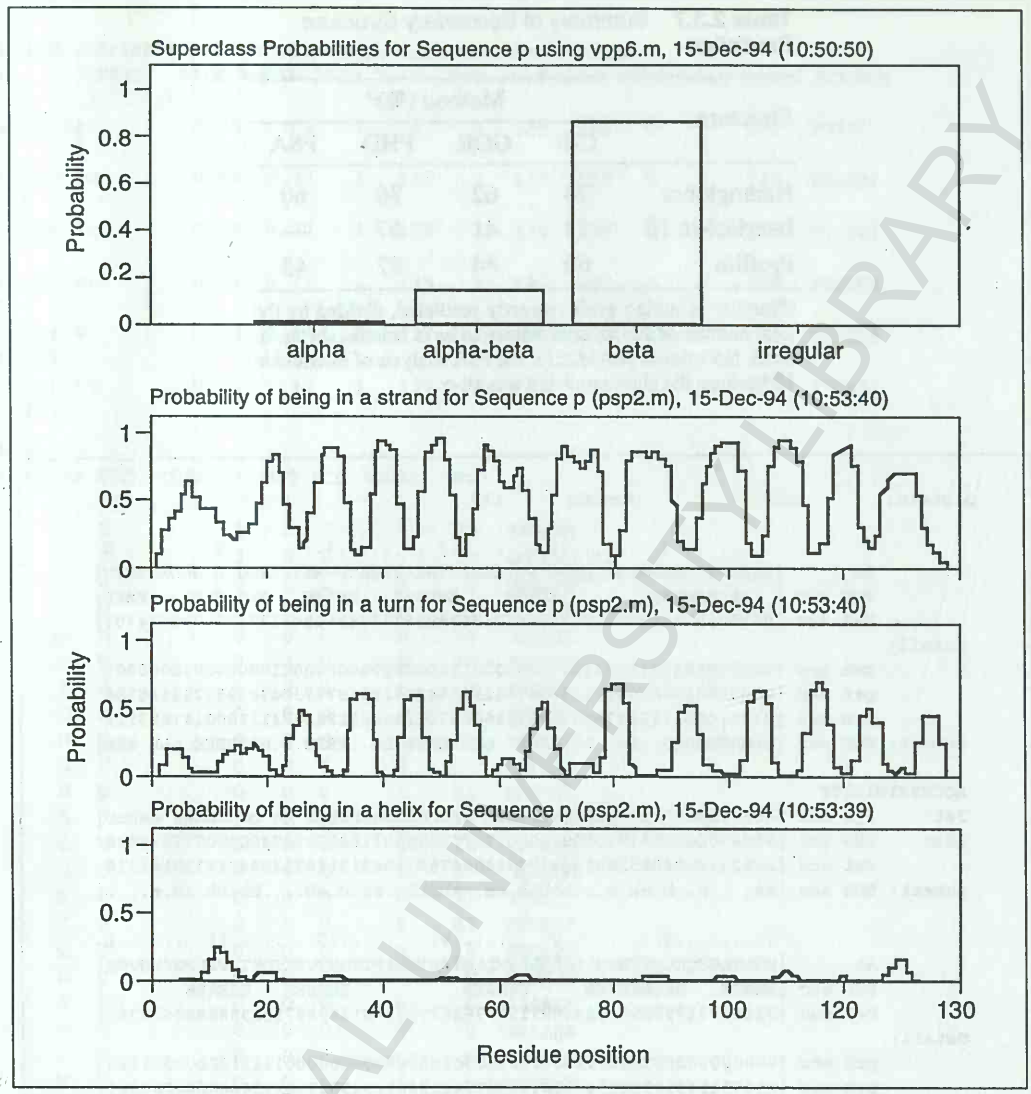

Figure 2.3.8 Class and secondary structure predictions for human profilin I with the PSA method.

to identify any protein whose structure is included in the Brookhaven Protein Data Bank for which there are no sequence homologs in sequence databases. If such a sequence and structure were available, the comparison of the predictive methods might have been less biased. However, this point highlights an advantage of the PHD method. Sequence homologs with known three-dimensional structures often help achieve an accurate prediction of secondary structure. The availability of homologous amino acid sequences imparts a significant predictive advantage to the PHD method in many cases.

RECOMMENDATIONS AND THE FUTURE

On the basis of the examples presented here and our experience in general, a combination of the Chou and Fasman interactive sequence analysis (which requires interpretation of the output data) and PHD neural network predictions (which are automatic) is recommended as the most accurate and preferable procedure.

As three-dimensional protein structural databanks grow, the future of protein structure prediction may lie with methods that "thread" the polypeptide sequence onto known motifs and evaluate the resulting model by pseudoenergetic analysis (e.g., PROSA; Sippl and Weitckus, 1992). Such programs currently exist, and successful fold identifications are being reported. However, the probability of a successful sequence-structure match is currently 10% (Sippl and Weitckus, 1992).

CONCLUSIONS

1. Empirically derived rules can aid sequence prediction using the GOR and Chou and Fasman statistical methods. Summaries of

RGU IAIN B. BANKS CENTRAL UNIVERSITY LIBRARY

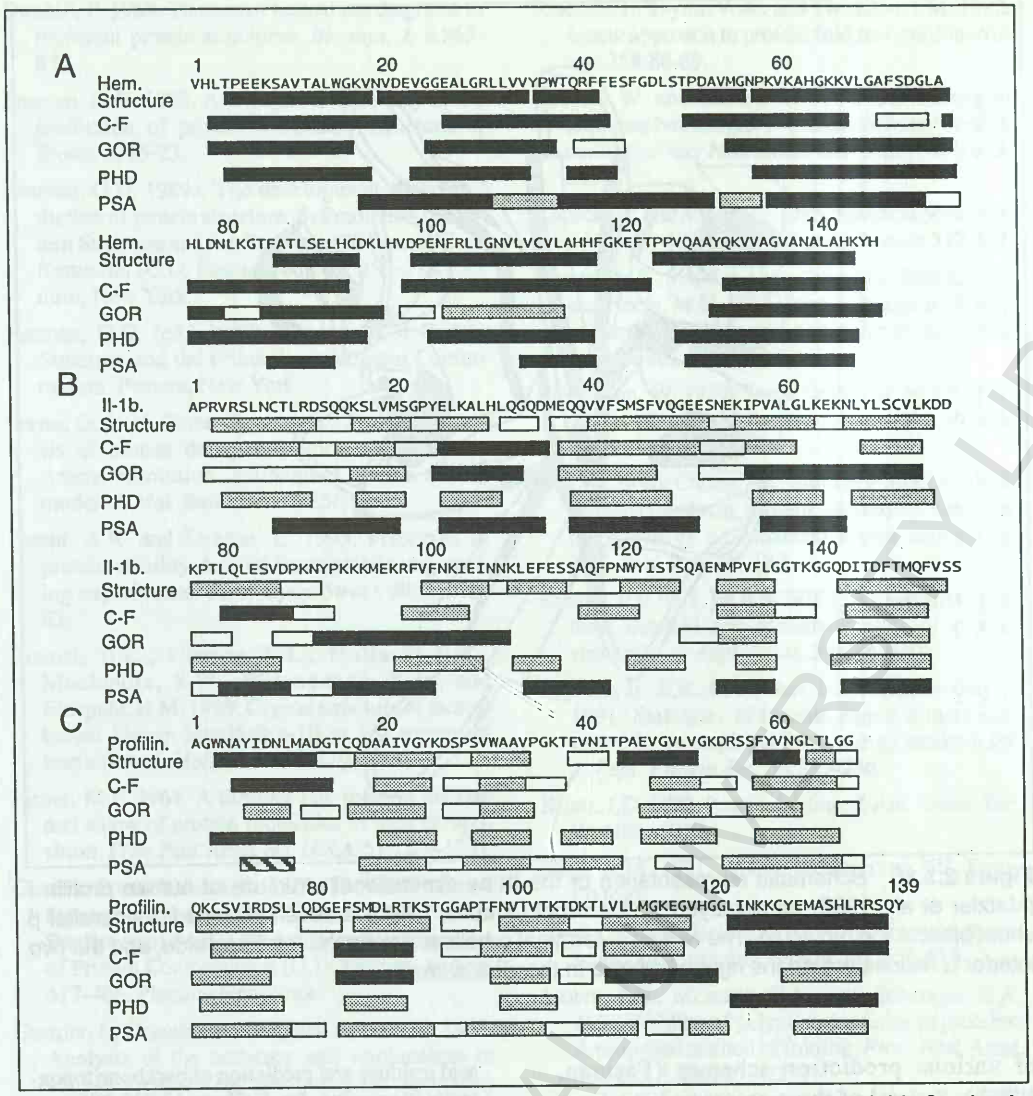

Figure 2.3.9 Summary of the secondary structure predicted for (**A**) human hemoglobin β-subunit, (**B**) human interleukin 1β, and (**C**) human profilin I. Each panel lists, from top to bottom, the amino acid sequence, the secondary structure determined experimentally, and the secondary structure predicted by each of the following: C-F, the Chou and Fasman method; GOR, the GOR method; PHD, the EMBL neural network method; and PSA, the state-space method. The location of helices (solid bars), turns (open bars), and sheet structure (hatched bars) are indicated.

these correlations (rules) are contained in Tables 2.3.4 and 2.3.5.

2. Methods that are open to interpretation do not guarantee the same result when applied by different users.

3. The PHD and PSA methods allow no input from the user, other than the sequence of interest, and thus are the easiest to use. For the other methods described here, the user can interactively participate in the prediction process.

4. If sequence homologs and, in particular, three-dimensional data are available, the PHD method gives reliable secondary structure predictions.

5. The PSA method was found to be less accurate than the other predictive schemes tested.

ACCESSIBILITY OF SOFTWARE

Several prediction schemes have been incorporated into commercial packages (e.g., GCG) that also contain algorithms for additional sequence analysis. Other packages have interactive graphics modules that combine sequence analysis with molecular displays (Tripos and Biosym); however, these packages do not easily incorporate additional user input. There have been numerous reports in the literature describing computerized implementation

Internet Basics

The Internet, more popularly known as the "information superhighway," has become a very pervasive influence in everyday life. Its power is most strongly seen among scientists, as more and more information is made available through "the Net," whether it be sequences, experimental data, chromosome maps, or whole journal articles. The aim of this unit is to provide a brief overview of what the Internet is, what kinds of information can be found on the Net, and how to use Internet tools to find and gather that information. The focus will be on practical examples, beginning with electronic mail and following the Internet timeline through to the development and use of the World Wide Web.

Despite the impression that the Internet is a single entity, it is actually a network of networks, composed of over 20,000 interconnected local and regional networks in more than 100 countries. The origins of the Internet go back to 1969, to a research project on networking at the Advanced Research Projects Agency of the United States Department of Defense named ARPANET. A number of different network projects subsequently surfaced, with the next landmark developments coming over ten years later. In 1981, BITNET ("Because It's Time") was introduced, providing point-to-point connections between universities for the transfer of electronic mail and files. In 1982, ARPA introduced the Transmission Control Protocol (TCP) and Internet Protocol (IP); TCP/IP allowed different networks to be connected to and communicate with one another, creating the system that is in place today.

Once the machines on a network are connected to one another, there needs to be some way to unambiguously specify a single computer so that messages and files find their intended recipient. To accomplish this, all machines directly connected to the Internet have an **IP address**. IP addresses are unique, identifying one and only one machine. The IP address is made up of four numbers separated by periods; for example, the IP address for the main file server at the National Center for Biotechnology Information (NCBI) at the National Institutes of Health (NIH) is *130.14.25.1*. The numbers themselves represent, from left to right, the domain (*130.14* for the NIH), the subnet (*.25* for the National Library of Medicine at NIH), and the machine itself (*.1*). While these IP numbers aid the computers in directing data, they are obviously very difficult for users to remember. Therefore, an IP address often has a **fully-qualified domain name** (FQDN) associated with it, which is dynamically translated in the background by a **domain name server**. Going back to the NCBI example, instead of using *130.14.25.1* to access the NCBI computer, a user could instead use *ncbi.nlm.nih.gov* and achieve the same result. Reading from left to right, the IP address goes from least to most specific, while the FQDN equivalent goes from most specific to least. The name of any given computer can then be thought of as taking the general form *computer.domain*, with the top-level domain (the portion coming after the last period in the FQDN) falling into one of the six broad categories shown in Table 2.4.1. Outside the United States, the top-level domain names are replaced with a two-letter code specifying the country where the machine is located (e.g., *.ca* for Canada and *.uk* for the United Kingdom).

CONNECTING TO THE INTERNET

Users who cannot plug their computers directly onto the Internet via an Ethernet, 10BaseT, or similar type of connection have two primary ways of accessing the Net: through **on-line services** or **Internet service providers** (**ISPs**). On-line services—e.g., America Online (AOL), CompuServe, and Prodigy—offer a large number of interactive digital services, including information retrieval, electronic mail (e-mail), bulletin boards,

and "chat rooms" where users who are on line at the same time can converse with each other about any number of subjects. While the on-line services now provide access to the World Wide Web (see discussion of The World Wide Web), most of the features and services available through these systems reside within a proprietary, closed network; once a connection is made between the user's computer and the on-line service, accessing the special features, or content, of these systems does not require ever leaving the on-line system's host computer. Specialized content can range from access to on-line travel reservation systems to encyclopedias that are constantly being updated—items that would not be available to anyone unless they subscribed to that particular on-line service. The focus on in-house content comes at a price; most of these services impose hourly charges for use, which can add up fairly quickly with even moderate use.

Internet service providers, or ISPs, take the opposite tack. Instead of focusing on providing content, the ISPs provide the tools necessary for users to send and receive e-mail, upload and download files, and navigate around the World Wide Web to find information at remote locations. Major players here include large firms such as AT&T and MCI. However, because it is not necessary for ISPs to provide content, a small cottage industry has quickly arisen, with many small, local firms providing reliable connections to the Internet. The major advantage of ISPs is connection speed; ISPs often provide faster connections than the on-line services. Most ISPs charge a monthly fee for unlimited use.

The distinctions between on-line services and ISPs have begun to blur in the favor of the on-line services. AOL recently changed its pricing structure to a monthly flat fee rather than per-hour charges, so for the same cost charged by many ISPs users can obtain all of the proprietary content found on AOL as well as all of the Internet tools available through ISPs. The extensive AOL network puts access to AOL as close as a local phone call in most of the United States, providing access to e-mail no matter where the user is located—a feature that small, local ISPs cannot match. Developments such as this, coupled with the move of local telephone and cable companies to providing Internet access through new, faster fiber optic networks, foretell major changes in how people will access the Net in the future, changes that should favor the end user both in price and performance.

ELECTRONIC MAIL

Most people are introduced to the Internet through the use of electronic mail (**e-mail**). The use of e-mail has become practically indispensable in many settings because of the convenience that it affords in sending, receiving, and replying to messages. Its advantages include the following:

1. it is much quicker than postal, or "snail mail";
2. it provides a convenient method by which messages can be filed or stored;
3. there is little or no cost involved in sending an e-mail message.

While these and other advantages have pushed e-mail to the forefront of interpersonal communication in both industry and the academic community, there are two major disadvantages that users should be aware of. First is the issue of security. As mail travels towards its recipient, it may pass through a number of remote nodes. The message could be intercepted and read at any one of those nodes by someone with high-level access, such as a systems administrator. Second is the issue of privacy. In industrial settings, e-mail is often considered to be an asset of the company for use only in official communication and, as such, is subject to monitoring by supervisors. The opposite is often true in academic, quasi-academic, or research settings; for example, National Institutes of Health policy encourages personal use of e-mail within the bounds of certain published guidelines. The key words here are "published guidelines"; no matter what the setting, users of e-mail systems should always be informed as to their organization's policy regarding the appropriate use and confidentiality of e-mail so that they may use the tool properly and effectively. An excellent, basic guide to the effective use of e-mail has recently been published and is highly recommended (Lamb and Peek, 1995).

Sending E-Mail

E-mail addresses take the general form *user@computer.domain,* where *user* is the name of the individual user and *computer.domain* specifies the actual computer that the e-mail account is located on. Like a postal letter, an e-mail message is comprised of an **envelope** or **header**, showing the e-mail addresses of the sender and recipient, a line indicating the subject of the e-mail, and information about how the e-mail message actually travelled from the sender to the recipient. The header is followed by the actual message, or **body**, analogous to what would go inside the postal envelope.

E-mail programs vary widely, depending on both the platform and the needs of the users. Usually the characteristics of the local area network (LAN) dictate what types of mail programs can be used, and the decision is often left to systems administrators rather than individual users. Among the most widely used e-mail packages with a graphical user interface are Eudora for the Macintosh and Microsoft Exchange for Macintosh, Windows, and UNIX platforms. Text-based e-mail programs, which are accessed by logging into a UNIX-based account, include Elm and Pine.

Sending E-mail using Pine

Since most Macintosh and IBM-compatible e-mail programs employing graphical user interfaces are fairly simple to use, we will concentrate here instead on Pine, one of the most widely-used UNIX-based mail programs available. To invoke Pine from the UNIX prompt, simply type:

```
unix> pine
```

where *unix>* represents the prompt and the characters in bold following the prompt represent what the user types at the keyboard. Once Pine starts up, the user will see a

Figure 2.4.1 Pine main menu.

menu presenting six major options (Fig. 2.4.1). Any one of these options can be selected either by using the arrow keys and then hitting the Return key or by simply typing in the single-letter command appearing at the left of each line. In order to compose a new e-mail, the user can simply hit the *C* key (for *Compose*) on the keyboard.

Once *C* is selected, a new screen appears, and the user can now fill in the e-mail address of the recipient, the subject of the message, and the actual message itself (Fig. 2.4.2). At the bottom of the screen are a number of commands that apply to this e-mail message, the two most important being *control-C* to cancel the message and *control-X* to send the message. Once either of these is entered, Pine asks for confirmation before sending or deleting the message.

Users can also "attach" files such as word-processing documents or spreadsheets to their e-mail messages. The attached file is sent with the e-mail message. The recipient can then save and use the attached file, provided that they have the appropriate software. To do so, the user would begin composing a message as described above. In order to begin the attachment, one would key in *control-J* to signify that a file is to be attached to the e-mail. At this point, Pine asks for the name of the file to be attached. If the user does not remember the file name, the user can type *control-T* to bring up a list of files from which the desired file can be selected (Fig. 2.4.3).

Files can be selected by moving around the list using the arrow keys on the keyboard. Files have their file sizes next to them, while subdirectories have *dir* listed next to them. When the desired file or directory is highlighted, press *S* for Select. Notice in the example that *parent dir* is highlighted; choosing *parent dir* moves the user one directory up in the file structure. Once a file is selected (rather than a directory), the user is returned to the *Compose* window, where a comment can be added to the e-mail message. At this point, the user can either type the comment and hit *Return*, or just hit *Return* if no comment is

BCU IASH FRONTIER UNIVERSITY LIBRARY

desired. Completion of the composition now resumes as described above. (Since Pine operates in the UNIX environment, the only files that can be attached to an e-mail message are those already on the UNIX machine. Also, even though a file is attached, the recipient may not be able to read the file if they are using a different mail package; consult your systems administrator for more details.)

Figure 2.4.4 Pine e-mail folder index.

Reading E-mail using Pine

To read received mail using Pine, starting from the main menu shown in Fig. 2.4.1 the user would type *I* for *Folder Index*. This produces a new screen listing all of the e-mail currently in the user's mailbox, both read and unread (Fig. 2.4.4). Each message has a message number followed by the date the message was sent, the name of the sender, the size of the message (in number of characters), and the subject of the message. A number of plus signs appear along the left-hand side of the message list, indicating that the message was sent solely to the recipient and is not a "carbon copy" (cc:) or part of a mailing list. Additional symbols that may appear in this position include *D* for Deleted, *N* for New, and *A* for Answered. The user can use the arrow keys to move up and down the list or can select a message by number. Once a message is selected (highlighted), simply pressing the *Return* key brings up the message for reading. To reply to a message at this point, one can type *R* for Reply. This will generate a new *Compose* window from which the recipient can reply to the sender. Automated replies to messages are system-dependent; users should ask their system administrator for further information on how to set up automated replies.

If one wishes to forward a message that has been received to another recipient, the user can highlight the message in the message list, then type *F* for Forward. A *Compose* window will appear with the text of the forwarded message in the message body. The user can add text to the message body as needed and then, send the message as described above.

Bulk E-Mail

As with postal mail, there has been a recent upsurge in "spam" or "junk e-mail," where companies compile bulk lists of e-mail addresses for use in commercial promotions. Since most of these lists are compiled from on-line registration forms and similar sources, the best defense for remaining off of these bulk e-mail lists is to be selective as to whom e-mail addresses are provided. Most newsgroups keep their mailing lists confidential; if in doubt and this is a concern, one should ask.

BCU IASH / CENTRAL UNIVERSITY LIBRARY

E-Mail Servers

So far, the discussion has centered on sending messages, whether it be to one or many recipients. It is also possible to use e-mail as a mechanism for making biological predictions or retrieving records from biological databases. Users can send e-mail messages in a predefined format, defining the action to be performed for remote computers known as **servers**; the servers will then perform the desired operation and e-mail back the results. Figure 2.4.2 actually shows such an e-mail request, using the BLAST e-mail server (see *UNIT 2.5*) at NCBI. While this method is not interactive (in that the user cannot adjust parameters or have control over the execution of the method in real time), it does place the responsibility of hardware maintenance and software upgrades on the persons maintaining the server, allowing users to concentrate on their results instead of on programming. An excellent, up-to-date list of e-mail servers is maintained by Amos Bairoch of the University of Geneva; this list can be obtained by anonymous file transfer protocol (described below) at *expasy.hcuge.ch*, moving to the */databases/info* directory, and downloading the file *serv_ema.txt*. For most of these servers, sending the message *help* to the server e-mail address will return a detailed set of instructions for using that server, including the way in which queries need to be formatted.

Aliases and Newsgroups

In the discussion above (see discussion of Sending E-Mail), the e-mail message is being sent to a single recipient. One of the strengths of e-mail is that a single piece of e-mail can be sent to a large number of people. The primary mechanism for doing this is through **aliases**; a user can define a group of people within their mail program and give the group a special name, or alias. Instead of using the individual e-mail addresses for all of the people in the group, the user can just send the e-mail to the alias name, and the mail program will handle broadcasting the message to each person in that group. Setting up alias names is a tremendous time-saver even for small groups; it also ensures that all members of a given group actually receive all e-mail messages intended for the group.

The second mechanism for broadcasting messages is through **newsgroups**. This model works slightly differently in that the list of e-mail addresses is compiled and maintained on a remote computer through subscriptions, much like magazine subscriptions. For example, the BIOSCI newsgroups are amongst the most highly-trafficked, offering a forum for discussion or the exchange of ideas in a wide variety of biological subject areas. To begin receiving the messages posted to the automated sequencing discussion group within BIOSCI, a user would send a message to *biosci-server@net.bio.net* with the wording *subscribe autoseq* in the body of the message. The user would then receive all future postings to that group and be able to participate in the discussions. If a user wished to be removed from the group, a message would be sent to the same address, but this time, the body of the message would read *unsubscribe autoseq*. For more information on BIOSCI, including a complete list of discussion groups, an e-mail message can be sent to *biosci-server@net.bio.net*; in this case the subject line should be left blank and the words *info faq* typed in the body of the message. The BIOSCI server will then return a copy of the Frequently Asked Questions (FAQ) in response, with detailed information on each newsgroup overseen by BIOSCI.

It is also possible to participate in newsgroups without having each and every piece of e-mail flood into one's private mailbox. Instead, interested participants can use newsreading software, such as NewsWatcher for the Macintosh, which provides access to the individual messages making up a discussion. The major advantage is that the user can pick and choose which messages to read by scanning the subject lines; the remainder can be discarded by a single operation. NewsWatcher is an example of what is known as a

This BIOSCI "miniFAQ" is designed to answer the questions that come up the *most frequently*. The main BIOSCI FAQ (Frequently Asked Questions) is accessible on the World Wide Web at URL http://www.bio.net/.
If you can not find an answer to your question in this or other documentation, the BIOSCI technical support staff answers e-mail queries sent to
biosci-help@net.bio.net
We can only answer questions about the use of the newsgroups and mailing lists. We unfortunately do not have the staff to do Internet information searches or answer scientific questions. Please post those to the appropriate BIOSCI/bionet newsgroups.
Contents:
0) BIOSCI NEEDS YOUR SUPPORT!!
1) Using the WWW to access the BIOSCI/bionet newsgroups.
2) What to do about "spams," i.e., junk mail, ads, etc.
3) Examples of subscribing and unsubscribing to the mailing lists.

Figure 2.4.5 NewsWatcher windows.

client-server application—the client software (here, NewsWatcher) runs on a client computer (a Macintosh), which in turn interacts with a machine at a remote location (the server). Client-server architecture is interactive in nature, with a direct connection being made between the client and server machines.

Once NewsWatcher is started, the user is presented with a list of newsgroups available to them (Fig. 2.4.5); this list will vary, depending on the user's location, as systems administrators have the discretion to allow or block certain groups at a given site. From the rear-most window in the figure, the user double-clicks on the newsgroup of interest (here, *bionet.genome.arabidopsis*), which spawns the window shown in the center. At the top of the center window is the current unread message count, and any message within the list can be read by double-clicking on that particular line. This, in turn, spawns the last window (in the foreground), showing the actual message. If a user decides not to read any of the messages, or is done reading individual messages, the balance of the messages within the newsgroup (center) window can be deleted by first choosing *Select All* from the *File* menu, then selecting *Mark Read* from the *News* menu. Once the newsgroup window is closed, the unread message count is reset to zero. Every time NewsWatcher is restarted, it will automatically poll the news server for new messages that have been created since the last session.

FILE TRANSFER PROTOCOL

Despite the many advantages afforded by e-mail in transmitting messages, experienced e-mail users have no doubt experienced frustration in trying to transmit files (**attachments**; see discussion of Sending E-Mail) along with an e-mail message. The mere fact that a file can be attached to an e-mail message and sent does not mean that the recipient

BCU IASTCOPY PALUNIVERSITY LIBRARY

will be able to detach, decode, and actually use the attached file. While more cross-platform e-mail packages such as Microsoft Exchange are being developed, the use of different e-mail packages by people at different locations means that sending files via e-mail is not an effective, foolproof method, at least in the short term. One solution to this problem is through the use of a **file transfer protocol** (or **FTP**). The workings of FTP are quite simple—a connection is made between a user's computer (the **client**) and a remote server, and that connection remains in place for the duration of the FTP session. File transfers are very fast, at rates on the order of 5 to 10 kilobytes per second, with speeds varying with time of day, distance between the client and server machines, and overall traffic on the network.

In the ordinary case, making an FTP connection and transferring files requires that a user have an account on the remote server. However, there are many files and programs that the academic community makes freely available, and access to those files does not require having an account on each and every machine where these programs are stored. Instead, connections are made using a system called **anonymous FTP**. Under this system, the user connects to the remote machine, and instead of entering a username/password pair, types *anonymous* as the username and enters an e-mail address in place of a password. Providing one's e-mail address allows the server's systems administrator to compile access statistics which may, in turn, be of use to those actually providing the public files or programs. As with the e-mail servers (see discussion of E-Mail Servers), Amos Bairoch also maintains an extensive list of molecular biology FTP servers. This list can be obtained by connecting to *expasy.hcuge.ch*, moving to the */databases/info* directory, and downloading the file *serv_ftp.txt*.

FTP on a UNIX-based system

For this example, an FTP session will be performed to download the aforementioned list of molecular biology FTP servers. The session begins from the UNIX prompt with the command *ftp*, followed by the name of the remote machine that the user wishes to connect to:

```
ftp expasy.hcuge.ch
```

The bold lettering indicates the characters typed at the keyboard. Once this command is issued, a connect request is made on the remote machine, and the remote machine subsequently asks for the user to log in. As this is an anonymous FTP server, users will type in *anonymous* as their user name, and their e-mail address as the password. The "password" itself will not appear when typing, but is shown below for the sake of example.

```
Connected to expasy.hcuge.ch.
220 expasy FTP server (Version wu-2.4.2-academ[BETA-14](1)
Wed Aug 27 14:44:30 MET DST 1997) ready.
Name (expasy.hcuge.ch:andy): anonymous
331 Guest login ok, send your complete e-mail address as password.
Password: scienceguy1@aol.com
```

Once the connection request is accepted, some introductory information about the FTP site may appear (lines labeled *230*), and eventually an *ftp>* prompt appears.

```
230-Please read the file README
230- it was last modified on Mon Sep 8 18:07:39 1997 - 66 days ago
230 Guest login ok, access restrictions apply.
Remote system type is UNIX.
Using binary mode to transfer files.
ftp>
```

BOWMAN-GITTENAL UNIVERSITY LIBRARY

At this point, the user may start to navigate the directories in the FTP site to find the file of interest. In this case, the user first needs to move to the */databases/info* directory, which is accomplished through a change directory (*cd*) command. The server responds that the "change working directory" (CWD) command was successful. The user may now request the file of interest with the *get* command; the list command (*ls*) can be used to check that the desired file is actually in the current working directory. Once the file transfer is complete, additional files may be downloaded, or the session may be terminated by typing *quit*. The session is terminated when the FTP server issues a *Goodbye*, and the user is returned to the local UNIX prompt.

```
ftp> cd/databases/info
250 CWD command successful.
ftp> get serv_ftp.txt
local: serv_ftp.txt remote: serv_ftp.txt
200 PORT command successful.
150 Opening BINARY mode data connection for serv_ftp.txt (44037 bytes).
226 Transfer complete.
44037 bytes received in 1.29 sec (33.32 Kbytes/s)
ftp> quit
221 Goodbye.
unix>
```

FTP using Fetch

While the above example is not particularly difficult to follow, it does require some basic knowledge and comfort with UNIX commands. Although FTP occurs within the UNIX environment, Macintosh and IBM-compatible computer users can employ programs that utilize graphical user interfaces (GUI, pronounced "gooey") to navigate through the UNIX directories on the FTP server and download files onto their non-UNIX machines. Users need not have any knowledge of UNIX commands to download files; they can instead rely on pop-up menus and the ability to point-and-click their way through the UNIX file structure. The most popular FTP program on the Macintosh platform for FTP sessions is Fetch. To illustrate the difference between UNIX FTP and Fetch, the same file used in the UNIX example above will be downloaded via Fetch on a Macintosh.

Once the Fetch application is launched, a window appears requesting the name of the remote server, the user's name, the user's password, and the target directory (Fig. 2.4.6). This one window combines the first several steps from the UNIX procedure into a single step once the OK button is clicked.

Upon connection, the user is presented with a list of the files appearing in the target directory (Fig. 2.4.7). There is a pull-down menu above the file list; this provides the user a way to "back up" and move out of a folder, back towards the root directory. The file of interest is highlighted by single-clicking its name with the mouse, and the file transfer is initiated when the *Get File* button is pressed. Notice in Figure 2.4.7 that the *Automatic* radio button (near the bottom of the window under the *Get File* button) is selected, meaning that Fetch will determine the appropriate type of file transfer to perform; this may be manually overridden by selecting either *Text* or *Binary*, depending on the nature of the file being transferred. The Macintosh will prompt the user for where the the downloaded file should be stored on the local system. Once a location is chosen, the file is transferred. The connection to the remote server remains in force until the window is closed or the user quits Fetch (using the command *apple-Q*).

In a similar fashion, Fetch can be used to upload files from a Macintosh to a remote computer. In this case, the steps are basically reversed—once the connection to the remote machine is established as described above, the user would simply click the *Put File* button instead. At this point, Fetch will bring up the Macintosh file-dialog window, asking which

BCU IAS CENTRAL UNIVERSITY LIBRARY

file should be uploaded. Once a file is selected, a second window will be spawned, asking how the file should be named once it is transferred to the remote machine as well as how the file should be transferred (most often as either *Text*, *Binary*, or *Raw Data*). As with *Automatic* downloads described in the preceding paragraph, Fetch will attempt to determine the proper protocol based on the type of file being transferred. As a rule, text files should be transferred as *Text*, programs or executables as *Binary*, and graphic format files such as PICT and TIFF files as *Raw Data*.

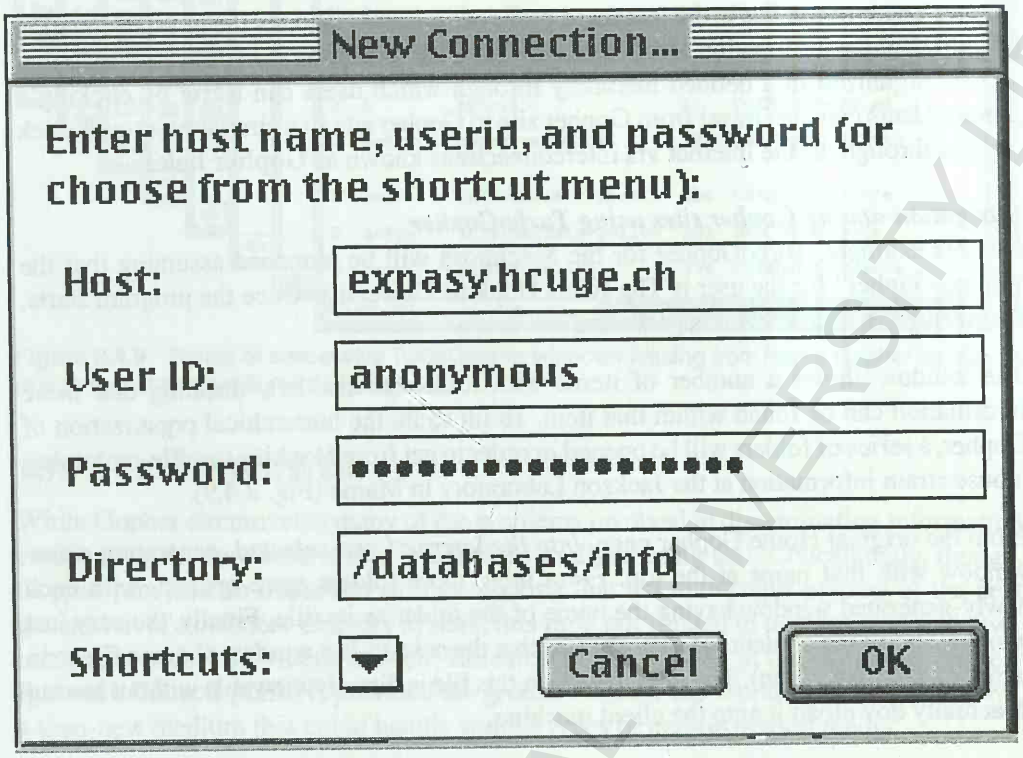

Figure 2.4.6 Fetch window for logging onto host.

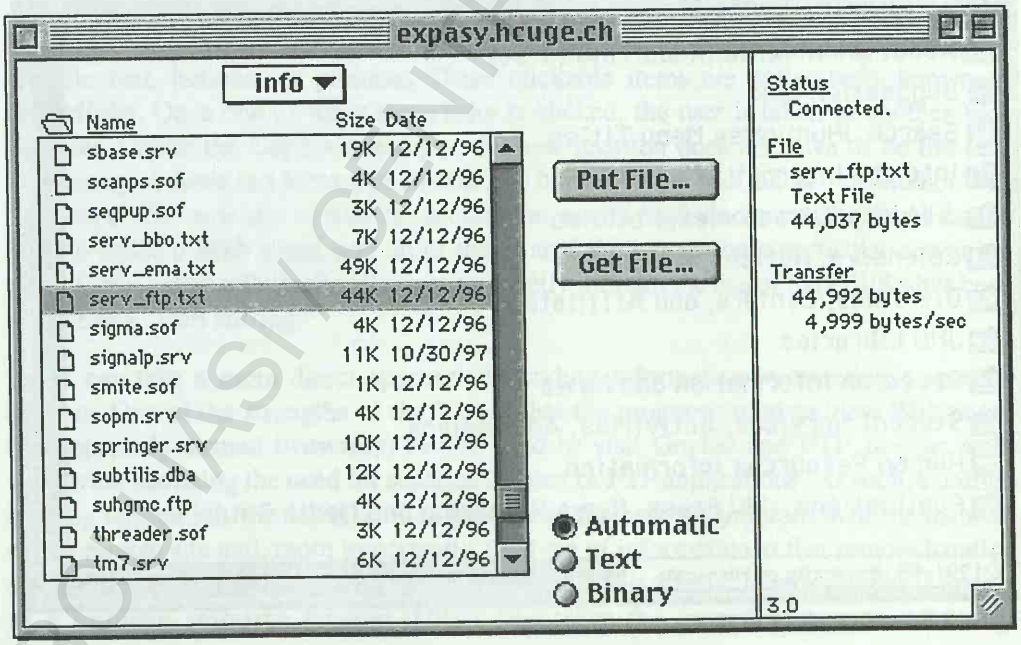

Figure 2.4.7 Fetch window showing files on remote host.

BOSTON CENTRAL UNIVERSITY LIBRARY

GOPHER

When working with FTP, once a user enters a particular directory, they can only see the names of directories or files. In order to actually view what is within those files, it is necessary to physically download files onto one's own computer. To circumvent this problem, researchers at the University of Minnesota developed a system through which text documents can be viewed without actually being downloaded. This program is named **Gopher** in honor of the school's mascot and is one of the first examples of a **distributed document delivery system**, a special type of interactive, client-server application.

Gopher's ease of use lies in the fact that a user does not need to know the physical location or address of the information being sought. All of the information stored at various Gopher sites is organized in a defined hierarchy through which users can travel by clicking a mouse. Users can also travel from Gopher site to Gopher site in a similar point-and-click fashion throughout the Internet via interconnections known as **Gopher holes**.

Navigation among Gopher sites using TurboGopher

For this example, TurboGopher for the Macintosh will be launched assuming that the "Home Gopher" for the user is The Johns Hopkins University. Once the program starts, the window in Figure 2.4.8 is generated.

The window shows a number of items with folders to the left, meaning that more information can be found within that item. To illustrate the hierarchical organization of Gopher, a series of folders will be opened in order to get from Hopkins to a file containing mouse strain information at the Jackson Laboratory in Maine (Fig. 2.4.9).

From the original Home Gopher page, *Into the Internet!* was selected, generating a new window with that name at the top. From there more folders were opened, with each newly-generated window having the name of the folder as its title. Finally, the very last window shows the contents of a file (notice that the next-to-last window shows a file icon rather than a folder icon). The information in this file is directly viewable without having to actually download it onto the client machine.

Figure 2.4.9 Series of successive TurboGopher windows leading from Home Gopher window in rear to text of a target file in the foreground.

THE WORLD WIDE WEB

While Gopher circumvents many of the problems involved in disseminating information easily, its main drawback is that it is limited to distributing text. Conceptually, though, Gopher provided an important shift in thinking that led to the development of the next generation of document-delivery system, this time not limited to text but able to deliver images, sounds, and videos as well. Research begun in 1989 at the European Nuclear Research Council (CERN) provided the groundwork for the World Wide Web (WWW), a then-new medium that could handle various types of non-text-based media.

Navigation on the World Wide Web

As with Gopher, navigation on the Web does not require advance knowledge of the location of the information being sought. Instead, users can navigate by clicking on specific text, buttons, or pictures. These clickable items are collectively known as **hyperlinks**. Once one of these hyperlinks is clicked, the user is taken to another Web location. Unlike the Gopher paradigm, the new location does not have to be the next location up or down in a hierarchy. Instead, the hyperlink can take the user to another Web location at the same site or halfway around the world. Each document displayed on the Web is called a **Web page**, and all of the related Web pages on a particular server are collectively called a **Web site**. Navigation strictly through the use of hyperlinks has been nicknamed "Web surfing."

Users can take a more direct approach to finding information by entering a specific address. One of the strengths of the Web is that the programs used to view Web pages (appropriately termed **browsers**) can be used to visit Gopher and FTP sites as well, somewhat obviating the need for separate Gopher or FTP applications. As such, a unified naming convention was introduced to indicate to the browser program both the location of the remote site and, more importantly, the type of information at that remote location so that the browser could properly display the data. This standard-form address is known as a **uniform resource locator** (**URL**), and takes the general form *protocol://com-*

BUDAPEST CENTRAL EUROPEAN UNIVERSITY LIBRARY

Table 2.4.2 Uniform Resource Locator (URL) Format for Each Type of Transfer Protocol

Site	URL format (example)
FTP site	*ftp://ftp.ncbi.nlm.nih.gov*
Gopher site	*gopher://gopher.iubio.indiana.edu*
Web site	*http://www.nhgri.nih.gov*
News site	*news:bionet.molbio.genbank*

puter.domain, where *protocol* specifies the type of site and *computer.domain* specifies the location (Table 2.4.2). The *http* used for the protocol in World Wide Web URLs stands for *hypertext transfer protocol*, the method used in transferring Web files from the host computer to the client.

Browsers

Browsers, which are used to look at Web pages, are client-server applications that connect to a remote site, download the requested information at that site, display the information on the user's monitor, then disconnect from the remote host. The information retrieved from the remote host is in a platform-independent format called **hypertext markup language (HTML)**. HTML code is strictly text-based, and any associated graphics or sound for that document exist as separate files in a common format. For example, images may be stored and transferred in GIF format, developed by CompuServe for the quick and efficient transfer of graphics; while GIF format is most commonly used for graphics, other formats such as JPEG and BMP may also be used. Because of this, a browser can display any Web page on any type of computer, whether it be a Macintosh, IBM-compatible, or UNIX machine. The text is displayed first, then the remaining elements are placed on the page as they are downloaded. With minor exceptions, a given Web page will look the same when the same browser is used on any of the above platforms.

One of the two major browsers is Netscape Communicator. Netscape, developed by Marc Andressen and colleagues, is the outgrowth of the first widely-used Web browser, NCSA Telnet (named for the National Center for Supercomputing Applications). Netscape was able to capture its large market share by basically giving its browser away for years, relying for revenue on Web servers and other products. While Netscape can still be freely downloaded from the Netscape Web site (see Table 2.4.3), newly-downloaded copies can be used free of charge only for the first 90 days (the fee is waived for educational institutions). Netscape does have some notable drawbacks, such as a clumsy bookmark system for storing the addresses of frequently visited sites, difficulty in displaying and navigating Web pages where the screens are split into separate frames, and a tendency to stall or crash frequently. However, it does a more than adequate job in addressing the Web-browser needs of most users.

Netscape's main competition comes from Microsoft, which is aggressively seeking to displace Netscape as the market leader with its own browser, Internet Explorer. Microsoft's strategy is to keep Internet Explorer a freeware product that can be downloaded directly from the Microsoft Web site (see Table 2.4.3). Internet Explorer has some key advantages over Netscape. Pages tend to load faster, the browser is more stable, and it handles frames much better than does Netscape. As the version numbers of both of these browsers advance, users will find many of the same features in both programs, and the final decision by users will come down to a matter of cost and personal preference.

It is worth mentioning that, while the Web is by definition a visually based medium, it is also possible to travel through Web space and view documents without the associated graphics. For users limited to line-by-line terminals, a browser called Lynx is available. Developed at the University of Kansas, Lynx allows users to use their keyboard arrow keys to highlight and select hyperlinks, using their return key the same way that Netscape and Internet Explorer users would click their mouse. Lynx is available for both the DOS and UNIX platforms (Table 2.4.3).

Internet versus Intranet

The World Wide Web is normally thought of as a way to communicate with people at a distance, but the same infrastructure can be used to connect people within an organization. Such **intranets** provide an easily accessible repository of relevant information, capitalizing on the simplicity of the Web interface. It also provides another channel for broadcast or confidential communication within the organization. Having an intranet is of particular value when members of an organization are physically separated, whether it be in different buildings or different cities. Intranets are protected in such a way that people who are not on the organization's network are prohibited from accessing the internal Web pages; additional protections through the use of passwords are also common.

BCU MAIN CENTRAL UNIVERSITY LIBRARY

Finding Information on the World Wide Web

Most people find information on the Web the old fashioned way—by word of mouth. Alternatively it is possible to find Web sites of interest either by using tables such as Table 2.4.3 or by simply following hyperlinks put in place by Web authors. Continuously clicking from page to page can be a highly ineffective way of finding information, especially when the information sought is of a very focused nature. One way of finding interesting and relevant Web sites is to consult **virtual libraries**, which are curated lists of Web resources arranged by subject. Virtual libraries of special interest to biologists include the WWW Virtual Library, maintained by Keith Robison at Harvard; Pedro's Biomolecular Research Tools, compiled by Pedro Coutinho at Iowa State; and the EBI BioCatalog, based at the European Bioinformatics Institutes. The URLs for these sites can be found in Table 2.4.3.

It is also possible to directly search the Web by using **search engines** such as Alta Vista and Excite, among others. A search engine is simply a specialized program that can perform full-text or keyword searches on databases that catalog Web content. The result of a search is a hyperlinked list of Web sites fitting the search criteria from which the user can visit any or all of the found sites. However, search engines use slightly different methods in compiling their databases. One variation is the attempt to visit and read data from all Web sites ("Web crawling"). Another technique is to catalog only the title of each Web page rather than its entire text. A third is to consider words that must appear next to each other or only relatively close to one another. Because of these differences in search-engine algorithms, the results returned by issuing the same query to a number of different search engines can produce wildly different results. Unless a particular search engine ranks its results by relevance (for example, by scoring words in a title higher than words in the body of the Web page), the results obtained may not be particularly useful.

To address this point, a new class of search engines called **meta-search engines** have been developed that take a more intelligent approach to Web discovery. These programs will take the user's query and poll anywhere from five to ten of the "traditional" search engines. The meta-search engine will then collect the results, filter out duplicates, and return a single, annotated list to the user. One big advantage is that the meta-search engines take relevance statistics into account, returning much smaller lists of results. Even though the hit list is substantially smaller, it is much more likely to contain sites that directly address the original query. Since the programs must poll a number of different search engines, searches conducted this way obviously take longer to perform, but the higher degree of confidence in the compiled results for a given query outweighs the extra few minutes (sometimes only seconds) of search time. Reliable and easy-to-use meta-search engines include SavvySearch and MetaCrawler (see Table 2.4.3).

As an example, let us consider the case where information on the mapping of human chromosome 7 is needed, but no Web address is at hand. In order to find such information without having to visit multiple search sites, a query will be issued through SavvySearch (*http://guaraldi.cs.colostate.edu:2000/form*). The Web form (Fig. 2.4.10) is rather simple to use, with a single box in which search terms can be typed. Here, the search terms *Chromosome 7 Mapping* have been entered; search results are better focused when more words of a specific nature are used. A variety of information sources can be searched, and a number of them have been checked off in the example. If no boxes are checked, SavvySearch defaults to checking Web resources only. Under query options, the most important choice to be made is in the pull-down menu labelled *Search for documents containing*. If *all query terms* is selected, all of the words must appear in the target document, but not in any given order or proximity. If *all query terms, as a phrase* is selected, the words must all appear, and they must all appear together in the order they

BCU IAS CENTRAL UNIVERSITY LIBRARY

were input in the query box. Finally, if *any query terms* is selected, only one of the words need appear in a target document in order for it to appear on the hit list; in practice, this option should never be selected, since it will bring back a large number of pages not really fitting the original query. By checking *Integrate results*, if the same hit is found by multiple search engines, it will only appear once on the final hit list presented to the user.

Figure 2.4.11 SavvySearch hit list.

DCU CENTRAL UNIVERSITY LIBRARY

The resultant hit list (Fig. 2.4.11) shows which search engines were used to produce the final hit list, as well as a list of documents fitting the search query as issued. For each hit, a hyperlink is provided that the user can click to go directly to that page. Also shown are the first few lines of the Web page, so that the user can assess whether that particular page is of use to them prior to actually loading the page. At the bottom of the page appears a box offering alternative *Search Plans*, which can be used to cast the net beyond the original set of search engines used in an attempt to find more hits. The SavvySearch team has made this engine available in, at last count, 23 languages—an indication of how truly global the Internet community has become in a relatively short period of time.

Sequence Similarity Searching Using the BLAST Family of Programs

Database "homology" searching is carried out thousands of times each day by scientists worldwide; it is a critical tool for all molecular biologists. The basic operation is to take a query sequence (consisting of either nucleotides or amino acids), compare it sequentially with all known sequences in a database, and rank the database sequences in a "hit list" with respect to how closely they resemble the query. The results may be positive, negative, or equivocal. The goal is to find sequences that are sufficiently similar to the query to justify an inference of functional similarity. The implicit hope is that the matching database sequence(s) will have a known function or phenotype that will shed light on the new sequence. It is less helpful if the match is to a sequence of unknown function, but it is still useful to know about homologs that exist in other organisms or as part of a multigene family, or that have been discovered previously in a different biological context.

The basic idea behind database searching is quite simple, but over the years a variety of sophisticated algorithms and statistical methods have been developed to detect and assess the significance of sequence matches. Recently it has been recognized that a number of additional factors greatly affect the efficiency of this method, including the choice of systems for assigning a score to a sequence alignment and the fact that proteins and genes are composite structures often made up of different structural and functional domains that possess different sequence properties. In addition, it cannot be assumed that sequence data is free of errors, and thus certain measures are necessary to ensure that no potentially important alignments are missed. A rigorous statistical method to assess the significance of alignment results is essential. The most important factor is to make sure that the database being searched is comprehensive and up-to-date. With thousands of new sequences entering the public databases every week, it is essential to have access to daily updates and to repeat searches periodically, particularly for those queries that yield no significant matches upon initial analysis.

BLAST, an acronym for "Basic Local Alignment Search Tool," represents a family of programs for database similarity searching (Table 2.5.1). BLAST programs embody a fast algorithm for sequence matching, rigorous statistical methods for judging the significance of matches, and various options for tailoring the program for special situations. A notable new feature is the ability to "mask" portions of the query sequence to reduce or eliminate spurious and misleading output (see Example 3). BLAST's implementations as an electronic mail (e-mail) service, as an Internet World Wide Web (WWW) page, and as a specialized client-server application (*UNIT 2.4*) to search daily updates of the sequence databases at NCBI, make it a very accessible and powerful tool.

OBTAINING BLAST DOCUMENTATION AND HELP

The most convenient way to access BLAST documentation is by using either e-mail or the WWW interface. For e-mail, send a message consisting of just the word "help" (without the quotes) to the normal BLAST server address (blast@ncbi.nlm.nih.gov). You will receive three e-mails in return: the help file for the BLAST e-mail server (e-mail help), the manual for the BLAST programs (manual), and the BLAST Frequently Asked Question file (FAQ). In addition to the above documentation files, the WWW BLAST interface includes on-line information about the BLAST theory and algorithm, bibliography, frequently-asked questions (FAQ), usage statistics, and a "what's new" feature. User support for any difficulties or problems encountered can be obtained by sending the question to blast-help@ncbi.nlm.nih.gov.

BOSTON COLLEGE UNIVERSITY LIBRARY

Table 2.5.1 BLAST Family of Programs for Database Similarity Searching

Program	Query sequence	Database sequences	Comments	Example
BLASTN	Nucleotide (both strands)	Nucleotide	Parameters optimized for speed, not sensitivity; not intended for finding distantly related coding sequences; automatically checks complementary strand of query	1,4
BLASTX	Nucleotide (six-frame translations)	Protein	Very useful for preliminary data containing potential frameshift errors, e.g., ESTs and other "single pass" sequences; 14 different genetic codes available; 65 different scoring matrices available; low-complexity filter options with SEG or XNU algorithms (highly recommended)	2,6
BLASTP	Protein	Protein	65 different scoring matrices available; low-complexity filter options	3
TBLASTN	Protein	Nucleotide (six-frame translations)	Essential for searching protein queries against dbEST; often useful for finding undocumented open reading frames or frameshift errors in database sequences; 14 different genetic codes available; 65 different scoring matrices available; low-complexity filter options with SEG and XNU algorithms (highly recommended)	5
TBLASTX	Nucleotide (six-frame translations)	Nucleotide (six-frame translations)	Restricted for search against dbEST, dbSTS, and Alu (except for e-mail server); 14 different genetic codes available; 65 different scoring matrices available; low-complexity filter options with SEG and XNU algorithms (highly recommended)	7

SUBMITTING SEQUENCES FOR DATABASE HOMOLOGY SEARCHING

Making use of remote BLAST services over the Internet (*UNIT 2.4*) offers several distinct advantages over performing searches on a local computer system. These include access to daily comprehensive updates of the sequence databases as well as to sophisticated software to run searches on computers that are much faster and more powerful than those generally available locally.

As outlined below, there are three main ways to submit a BLAST query for remote execution. Regardless of which method is used, there are four basic elements common to all BLAST requests:

1. The BLAST command to be executed;
2. The name of the database to be searched;
3. Additional parameters and modifiers (optional); and
4. The query sequence.

In a short period of time, usually measured in minutes, you will receive the results (BLAST output) of your search. Then you must evaluate whether or not anything interesting was found. There are two basic steps to this process.

BJU IASRI CENTRAL UNIVERSITY LIBRARY

First, determine if any matches are statistically significant. Keep in mind that for any query sequence, all database search programs will produce an ordered list of aligned sequences, but none of them need have any biological significance. The question is what degree of similarity is necessary to be considered surprising—i.e., not likely to have occurred by chance. For each database match, BLAST produces a *p* value derived from the application of a rigorous theory for the assessment of sequence similarities (see Commentary for a detailed discussion of this topic).

Second, assuming some significant or potentially significant matches are found, retrieve the full database records for the sequences of interest to examine their annotation, which often has more extensive information on function, expression, and other topics of interest. The database record also provides links to the scientific literature. The basic procedure is to use the sequence accession number as a key to obtain the database record and associated literature using either e-mail or Internet client-server resources (*UNIT 2.4*). NCBI's RETRIEVE server (accessible by e-mail), World Wide Web/Mosaic page, and Entrez system (available over the Internet, on CD-ROM, and is also included on *Current Protocol on CD-ROM*) are specific examples.

BLAST searches are available via e-mail and a WWW interface and as an Internet service using a command-line interface. All three applications are described in more detail below. E-mail is ubiquitous, convenient, and well-suited to those who only submit occasional queries. The WWW interface makes it easy to "copy and paste" sequences for searching. The command-line interface is the most powerful way to use BLAST and is easy to incorporate into automated systems for high-throughput analysis.

Submitting a Sequence to BLAST Using the Electronic Mail Server

BASIC PROTOCOL 1

Materials

Any computer system and a means of composing, sending, and receiving e-mail
BLAST e-mail server help file (see *UNIT 2.4*; optional but highly recommended)
Query sequence file(s) in FASTA/Pearson format (see Example 1)

NOTE: Most commercial sequence analysis software packages provide file interconversion routines that produce FASTA/Pearson format. A free, public-domain program called READSEQ can interconvert more than a dozen different formats, including FASTA/Pearson. READSEQ, written by Don Gilbert, is available via Gopher or anonymous FTP (see *UNIT 2.4*) from ftp.bio.indiana.edu in the /molbio/readseq directory. Note that the BLAST programs are not case-sensitive with regard to query sequences, which therefore may consist of either upper- or lower-case letters.

1. Create new mail and address it to blast@ncbi.nlm.nih.gov. It is not necessary to supply a subject line, but if one is provided, the server will use it in the subject of its reply.
2. In the body of the message, type the keyword PROGRAM followed by the name of the BLAST command to be executed (BLASTN, BLASTP, BLASTX, TBLASTN, and TBLASTX are available; see Table 2.5.1 and the BLAST e-mail help file for more details).
3. On the next line, type the keyword DATALIB followed by the name of the desired database. Although we use genbank in Example 1 for simplicity, we recommend using nr, which is a comprehensive, quasi-nonredundant superset of GenBank plus nucleotide sequence data from other sources.

BCM/SJCH CENTRAL INVENTORY LIBRARY

4. Start a new line and type the keyword BEGIN to indicate the beginning of your query sequence. Insert the contents of a FASTA-formatted sequence file into the mail message beginning on the next line.
5. Insert a blank line to indicate the end of the sequence (see the FAQ file, questions 17 and 29, for more details).
6. Send the message. You will receive the results by return e-mail, usually within 1 hr. Occasionally it will take longer than this, due to heavy loads on the system or server maintenance. If you do not receive a reply by the next morning, contact NCBI at the BLAST help address, blast-help@ncbi.nlm.nih.gov, or by telephone at 301-496-2475.

Note that many other parameters may be applied to BLAST searches. Some of these are described below. A complete description of e-mail server directives and their uses is included in e-mail help, which also includes descriptions of available databases and an explanation of sequence identifiers.

BASIC PROTOCOL 2

Submitting a Sequence to BLAST Using the Command-Line Client Program

Materials

UNIX computer with TCP/IP and BSD socket support, Ethernet hardware, Internet connection, and C compiler
Suite of BLAST programs appropriate for the computer system
Query sequence file(s) in FASTA format (see Example 1)

NOTE: Compatible operating system support for TCP/IP and BSD sockets is provided by Sun Microsystems, Silicon Graphics, Hewlett-Packard, Digital Equipment Corporation, and IBM. Many modern UNIX workstations come with Ethernet hardware built in. If these terms are unfamiliar to you, please consult your local systems manager for more information.

NOTE: The source code for BLAST programs is available at NCBI via anonymous FTP (ftp to ncbi.nlm.nih.gov) beneath the BLAST directory.

1. At the console command prompt, type the following items in order, separated by spaces:
   a. The BLAST command (e.g., blastn);
   b. The name of the database (e.g., genbank); and
   c. The name of a file containing your query sequence.
2. If desired, change default search parameters or enter optional parameters after the BLAST command on the same line, separated by spaces. A complete list of parameters and options, their syntax and uses are described in the BLAST manual file.
3. It is normally desirable to capture the output in a disk file (by default, it would only be displayed on the console). To do this under UNIX, include in your command the redirection symbol > followed by the name of a file.
4. Press the Enter key to execute the command.

BRU IAS/CENTRAL UNIVERSITY LIBRARY

Submitting a Sequence Using NetBLAST Graphical Client Program

BASIC PROTOCOL 3

Materials

One of the following computer systems equipped with a network interface and having the ability to access the Internet (*UNIT 2.4*):
- Macintosh computer running System 7.0 (or later) operating system and MacTCP system extension
- IBM-compatible computer running Microsoft Windows 3.1 (or later) and any network software package that supports the WinSock specification

NetBLAST–executable program appropriate for the system
Query sequence file(s) in FASTA format (see Example 1)

NOTE: The NetBLAST executable program will be included on *Current Protocols on CD-ROM*. Contact NCBI at net-info@ncbi.nlm.nih.gov or 301-496-2475 regarding current availability.

1. Start the NetBLAST program (see Example 4).
2. As the program begins, a File-Open dialog box will appear. Enter or select the name of a file containing the query sequence. After selecting the query sequence, press the OK button to continue.
3. Another dialog box will appear listing options to further define the search conditions. The settings are organized into categories, represented by "folder tabs" across the top of the window. Click on the Database tab.
4. Select the database type (nucleotide or protein) that you want to search. If the query is a nucleotide sequence, you may check the Translate query option to search a protein database.
5. A list of databases of the given type will be displayed; select the one you want to search.
6. Select other tabs to examine or modify additional parameters by clicking on them (optional).
7. Press the Search button to send the request to the server. When the results are returned, they will be displayed in a window.

Submitting a Sequence Using the WWW Interface

BASIC PROTOCOL 4

Materials

One of the following computer systems equipped with a network interface and the ability to access the Internet (see *UNIT 2.4*):
- UNIX computer with TCP/IP and BSD socket support and Ethernet hardware
- Macintosh computer running the System 7.0 (or later) operating system and the MacTCP system extension
- IBM-compatible computer running Microsoft Windows 3.1 (or later) and any network software package that supports WinSock

WWW browser–executable program appropriate for the system
Query sequence file(s) in FASTA format (see Example 1)

NOTE: Browsers may be obtained at one of the following FTP sites: ftp.ncsa.uiuc.edu for NSCA (UNIX, Mac, Windows), ftp.mcom.com for Netscape (UNIX, Mac, Windows), or ftp.einet.net for EINET (Mac, Windows).

BOSTON CENTRAL UNIVERSITY LIBRARY

1. Start the WWW browser–executable program.
2. Open a new URL to http://www.ncbi.nlm.nih.gov/, then click to go to the WWW BLAST Search page.
3. Click in the pop-up menus to specify the search parameters.
4. Cut the query sequence file from the sequence data and paste it into the Sequence field.
5. Click the Perform Search button.

   The results will be displayed in the browser window.

EXAMPLE 1: USING BLASTN TO SEARCH A NUCLEOTIDE SEQUENCE DATABASE WITH A DNA SEQUENCE

In this example the cDNA sequence of human MLH1 (GenBank accession numbers U07343 and U07418) is used to search GenBank for related nucleotide sequences. MLH1 is a gene on chromosome 3p21-23 that is associated with hereditary nonpolyposis colon cancer (Bronner et al., 1994; Papadopoulos et al., 1994). The results of this search (BLASTN output) are shown in Figures 2.5.1 to 2.5.4.

Using BLAST Electronic Mail Server

```
-------------------------------------------------------------------
mail blast@ncbi.nlm.nih.gov
Subject:

PROGRAM blastn
DATALIB genbank

TACACAGTGGATTGATTATAAATAAATAGATGTGTCTTAACAT
-------------------------------------------------------------------
```

Using BLAST Command-Line Client Program

The command-line equivalent of the above BLASTN search is:

```
-------------------------------------------------------------------
my_computer> blastn genbank hmlh1.seq > hmlh1_genbank.blastn
-------------------------------------------------------------------
```

where my_computer is the command prompt on your system, hmlh1.seq is a file containing the sequence in FASTA format, and the > symbol instructs UNIX to save the output in a file named hmlh1_genbank.blastn

Discussion

The hit list produced by a BLASTN search (Fig. 2.5.2) is the most important part of the output: it is what researchers visually scan in their initial evaluation of the results. Each line of the hit list is composed of five fields (an additional field indicating the reading frame is included when BLASTX, TBLASTN, or TBLASTX is used). The first field contains a database designation, accession number, and locus name for the matched sequence separated by vertical bars. So, for the first hit, the database designation is gb (for

Figure 2.5.2 Information regarding the query sequence and database searched followed by the hit list for the BLASTN search in Figure 2.5.1.

GenBank), the accession number is U07418, and the locus name is HSHMLH1. The second field contains a brief textual description of the sequence, also known as the definition line. The content of this definition line varies between and within databases but usually includes information on the organism from which the sequence was derived, the type of sequence (e.g., mRNA or DNA), and some clue about function or phenotype. The definition line is often truncated in the hit list to keep the display compact but is fully displayed in association with the local alignments. The third field contains the alignment score, based on the scoring matrix used, for the best ungapped local alignment ("high-scoring segment pair" or HSP) between the query sequence and the database sequence. The fourth field contains a *p* value indicating the probability that the match could have occurred by chance and the fifth field indicates the number of HSPs in the set that resulted in the lowest *p* value. The third section of the output (Fig. 2.5.3) contains the sequence alignments prefaced by more complete descriptions of the database sequences and statistical results. Alignments found with the BLAST algorithm are ungapped. Several statistics describe each HSP: the raw alignment score; the raw score converted to bits of information; the number of times this match or a better one might occur merely by chance; the *p* value (probability in the range 0 to 1) of observing such a match; the number and fraction of total residues in the HSP that are identical; the number and fraction of residues for which the substitution scores have positive values; and, for nucleotide sequences, the strand of the query that resulted in the match. Between the two lines of Query and database (Sbjct) sequence is a line indicating by the symbol "|" the specific nucleotides that are identical; a blank space is left between those that are nonidentical. (Note that the convention is different for protein sequence alignments; see Sample 1 below). The section following the alignments at the end of the output (Fig. 2.5.4) contains a summary of the run parameters and statistics. Note that this search of 269,478 sequences using a 2503-nucleotide query took only 25 seconds (Total cpu time). The summary indicates that the BLAST results are complete.

Although it is not relevant to this example, BLASTN automatically checks the complementary strand of the query sequence. Note that BLASTN is optimized for speed, not sensitivity, and it is not intended for finding distantly related coding sequences (for comparison see Example 2). The small DNA alphabet (four letters) compared with proteins (twenty letters) and the degeneracy of the genetic code makes searches using the encoded protein sequence much more sensitive, as illustrated with the BLASTX and BLASTP searches below.

Figure 2.5.3 Sequence alignments prefaced by more complete descriptions of the database sequences and statistical results for the BLASTN search in Figure 2.5.1. The two top (self) alignments from Figure 2.5.2 are omitted for brevity.

For proteins, it is also possible to take into account conservative amino acid substitutions (see Scoring Systems and Alignment Statistics in Commentary).

The BLAST programs have many options that alter the sensitivity, specificity, and speed of the search and specify different scoring systems, alternate genetic codes, etc. The examples show only the simplest cases. We illustrate the filter option (-filter command; see Example 3); a complete list of options and parameters is described in the BLAST help file. Note that there are certain restrictions to the list of available options provided by the BLAST e-mail server (see the e-mail help file). Options for the BLAST programs (Table 2.5.1) are preset to certain default parameters that are generally most useful. For tips on altering these parameters to address special situations, see Commentary.

Figure 2.5.4 Summary of the run parameters and statistics for the BLASTN search in Figure 2.5.1.

EXAMPLE 2: USING BLASTX TO SEARCH A PROTEIN SEQUENCE DATABASE WITH OPEN READING FRAMES DERIVED FROM CONCEPTUAL TRANSLATIONS OF A DNA QUERY SEQUENCE

Suppose that for the DNA sequence in Example 1 the precise location of the translation initiation or termination codons was not known. Or suppose that the sequence was from genomic DNA and it was not clear whether it contained any coding sequences at all. Perhaps the data were derived from single-pass automated sequencing and contained some frameshift errors or nonsense mutations causing premature termination. In compact genomes such as those of yeast and prokaryotes, where the intergenic distances are small, there may be another gene upstream or downstream of the gene of interest. These are all "real world" contingencies that BLASTX was designed to handle (Gish and States, 1993).

In this example, the database designation nr refers to NCBI's non-redundant sequence database. The output of this search is shown in Sample 1 and in Figure 2.5.5.

Using BLAST Command-Line Client Program

The command-line equivalent of the above BLASTX search is:

```
-----------------------------------------------------------------
my_computer> blastx nr hmlh1.seq > hmlh1_nr.blastx &
-----------------------------------------------------------------
```

In this command-line example, the ampersand (&) instructs UNIX to run this job as a background process. Because BLASTX is translating the nucleotide query in all six reading frames, this search will generally take longer than a BLASTN search, depending on the size of the database, and it is wise to run such searches in the background. This caution also applies to the TBLASTN program (Example 5).

Sample 1: Output from Example 2 Search

Discussion

There are several differences between the hit list from a BLASTX search (Fig. 2.5.5) and the list from a BLASTN search (Fig. 2.5.2). First, because NCBI's nr nonredundant database was searched, the database designations are variable, reflecting the source databases used to build nr. For example, gp indicates a GenPept translation of a GenBank sequence and sp indicates Swiss-Prot was the source database. More complete descriptions of the database cross-references are included in the long header lines associated with the alignments in Sample 1. The second difference is the presence of the reading frame

```
Query=  gi|466461|gb|U07418|HSHMLHI Human DNA mismatch re...
        (2503 letters)

  Translating both strands of query sequence in all 6 reading frames

Database:  Non-redundant PDB+SwissProt+SPupdate+PIR+GenPept+GPupdate
           143,811 sequences; 41,308,423 total letters.
Searching.....................................................done

BLAST shows the top 100 matches by default; only the first 20 are included to save space.

Figure 2.5.5 Contents of return message from BLAST e-mail server containing BLASTX search results from Example 2. Hit list. Text in italic is added by the author.

UCSF CENTRAL UNIVERSITY LIBRARY

in the third field of this hit list. +3 indicates the third reading frame on the query sequence and −1 designates the first reading frame on the complementary strand. The main difference in the alignments (Sample 1) is the labeling of exact matches and conservative amino acid substitutions. An amino acid identity between two aligned sequences is indicated by simply repeating the single-letter code symbol for that residue. Conservative substitutions are indicated by a plus (+) sign; an amino acid substitution is defined as conservative if it has a replacement score of ≥0 in the matrix used for the alignment. In Example 1, there happened to be only a single HSP for each query/database match. In the present example most matches consist of multiple HSPs, and these are reported not in order of their occurrence in the linear sequences of the proteins, but rather in order of their degree of similarity. This is one of the difficulties for beginners (who are used to seeing more extensive alignments with gaps) in trying to understand and interpret the BLAST output. The best of both worlds is provided by the NetBLAST graphical interface (see Example 6), which not only displays the global relationships schematically (Fig. 2.5.10B) but also provides point-and-click access to the textual representations of all reported local alignments. Because all six reading frames of the query had to be tested against the database, this search took several times longer than the BLASTN search in Example 1.

BLASTX is very useful for analyzing preliminary sequence data containing potential errors (Gish and States, 1993) and is essential for analyzing expressed sequence tags (ESTs; Boguski et al., 1993, 1994) or genomic sampling sequence data (Smith et al., 1994). Because these data are usually generated by single-pass sequencing, the error rate is ~1% to 3%. Moreover, the coding potential is not known in advance, making six-frame translations necessary.

Note that, in this search involving conceptual translations of the nucleotide query, the "standard" or "universal" genetic code is used by default. For scoring the amino acid alignments, the BLOSUM62 matrix is the default system. As noted, either of these parameters can be changed if appropriate. For further information see Commentary.

EXAMPLE 3: USING BLASTP TO SEARCH A PROTEIN SEQUENCE DATABASE WITH A PROTEIN SEQUENCE QUERY USING THE FILTER OPTION TO MASK LOW-COMPLEXITY SUBSEQUENCES

In this case we will again search the nr database, this time using the translated protein sequence of MLH1 (Example 1) as the query and "masking" low-complexity subsequence in the query using the seg algorithm (see below). Note that the manner or syntax for specifying this filter option is slightly different in the e-mail and command-line versions. The results of this search, showing the effects of query masking, are given in Sample 2 and in Figure 2.5.6.

           MLH1). >pir|S43085|S43085 MLH1 protein - human
           >gp|U07343|HSU07343_1 hMLH1 [Homo sapiens]
           Length = 756

 Score = 3734 (1702.5 bits), Expect = 0.0, P = 0.0
 Identities = 729/756 (96%), Positives = 730/756 (96%)
```

Alignment omitted for brevity.

The following alignment is identical to that produced by the BLASTX program in Sample 1. However, note the variation in numbering. Here amino acid residues 8 through 229 correspond to nucleotides 39 through 623 in Sample 1. Sample 1 also includes the translation frame information, e.g., "Frame = +3."

Discussion

There are two striking differences between the hit list produced by BLASTP (Fig. 2.5.6) and that of the BLASTX search with the same query (Fig. 2.5.5); both are due to masking of low-complexity subsequences using the SEG filter option. This hit list contains only 47 matches (compared with 356 matches), and also the identities of the matches are completely different (and inconsistent) following the ninth match in both lists. Low-complexity subsequences identified by the SEG algorithm are masked by replacing the amino acid codes with "X"; two such subsequences (residues 365 to 375 and 475 to 486) can be seen in the first alignment. BLAST ignores these X-masked segments. The first segment is proline-rich and the second segment has a high proportion of acidic—Glu (E) and Asp (D)—residues. These low-complexity subsequences represent less than 3% of the query sequence, yet their removal has a dramatic impact, shrinking the output by reducing the number of spurious matches and greatly improving the signal-to-noise ratio.

It cannot be stressed enough how useful it is to filter and mask low-complexity subsequences using the SEG and/or XNU algorithms and a thorough discussion of this important topic is included (see Low-Complexity Sequences and Masking Low-Complexity Sequences in Commentary). Masking procedures are absolutely essential when faced with analyzing the output of high-throughput sequencing where, for obvious practical reasons, human intervention in the sequence analysis process must be streamlined as much as possible.

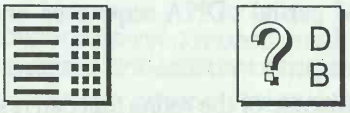
Figure 2.5.6 Contents of return message from BLAST e-mail server containing BLASTP search results from Example 3. Hit list.

EXAMPLE 4: USING THE WWW INTERFACE

Here we illustrate the use of the WWW BLAST interface by repeating the search described in Example 1 but with the nucleotide nonredundant database.

Figure 2.5.7 shows the WWW BLAST interface Search page. Pop-up menus (marked by the arrows) allow the user to define the kind of search needed by choosing the type of program, the database, and the BLAST options available through this interface. This example (Fig. 2.5.7) uses the default parameters. Click on each of the underlined words (e.g., Program, Expect, Cutoff) to see on-line documentation about the items. Insert comments about the sequence into the Comment field. Insert the sequence into the Query Sequence field simply by copying and pasting it from the sequence file. Then click on Perform Search to run the search. Once the search is done, the results are returned in the WWW browser window. Figure 2.5.8 shows the Output page with the hit list and the beginning of the first alignment.

Two features allow you to move back and forth in the BLAST output and are very useful for large BLAST output files. First, at the level of the hit list, clicking on the underlined part of one of the hit list lines moves you directly to the corresponding alignment. Second, each alignment has two buttons (see Fig. 2.5.8 and Sketch 2.5A): clicking on the left-hand button moves you back to the hit list; clicking on the right-hand button retrieves the entry of the matched sequence from the database and displays the entry on screen (see Fig. 2.5.9). This example shows the GenBank entry U07418 corresponding to a human mismatch repair mRNA. To move back to the BLAST Output page, click on the Back button of the WWW browser.



Sketch 2.5A

BCU IAS / CITY AS UNIVERSITY LIBRARY

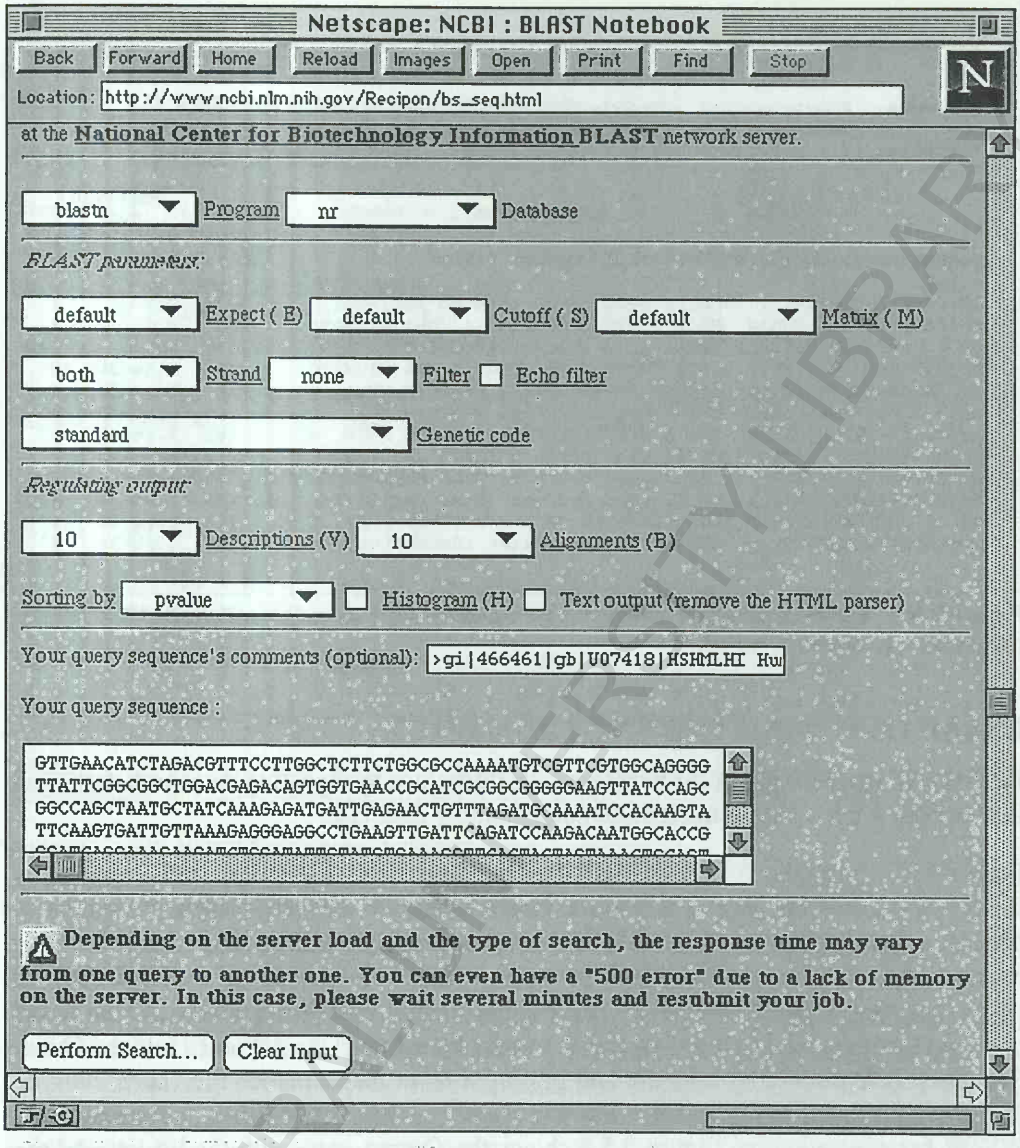


Figure 2.5.7 The WWW interface of the BLAST network server (see Example 4): Search page.

EXAMPLE 5: USING TBLASTN TO SEARCH A TRANSLATED NUCLEOTIDE DATABASE WITH A PROTEIN SEQUENCE

TBLASTN performs a function complementary to BLASTX (Example 2); i.e., whereas BLASTX translates the nucleotide query sequence in all six frames, then searches a protein database, TBLASTN takes a protein query sequence and compares it against six-frame translations of a nucleotide sequence database. As this latter procedure requires a great deal of computation, it should not be undertaken lightly on large nucleotide sequence databases. Nevertheless, the reality is that nucleotide sequence databases do contain errors and undocumented coding sequences making TBLASTN an important part of the database searching toolkit. TBLASTN is essential for searching protein queries against dbEST, a collection of partial cDNA sequences or "expressed sequence tags" (Boguski et al., 1993, 1994).

Choroideremia is an X-linked disease of the retina that can result in blindness (McKusick, 1994). The gene responsible encodes a 95-kDa protein that we will use as a query sequence.

Discussion

The results of searching the human choroideremia protein query against dbEST are shown in Sample 3 (the reading frame in this case is that of the database sequence). Note that there are fourteen significant hits. There are seven matches from human proteins, four matches to nematode proteins, and three matches to plant sequences (rice and *Arabidopsis*). Given the vast evolutionary distance between mammals, nematodes, and plants, it is doubtful that these sequence similarities would be detectable on the nucleotide level and indeed they are not detected if one uses BLASTN to search dbEST with the choroideremia cDNA sequence (not shown).

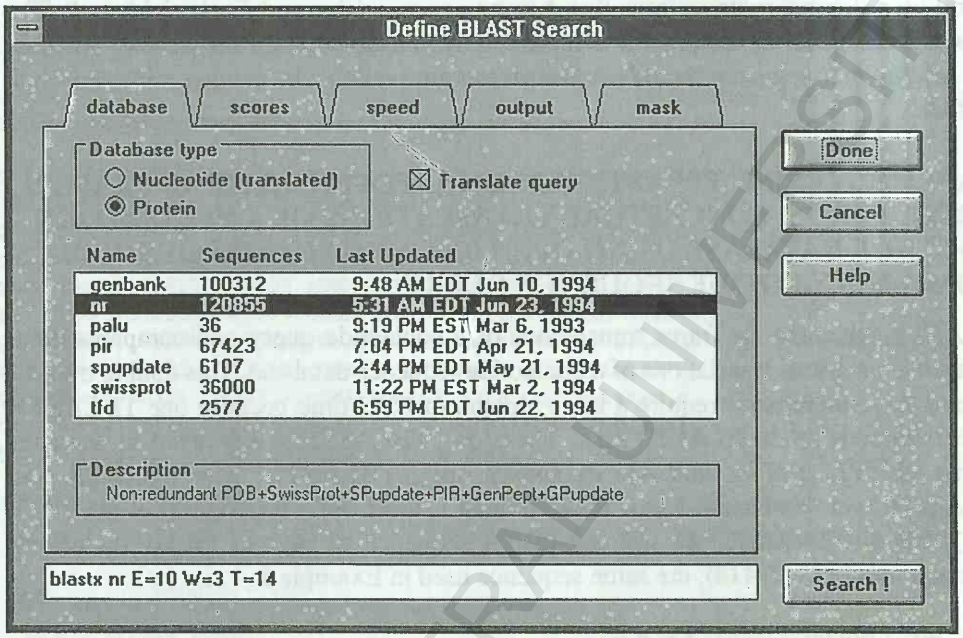
As in the BLASTX example (Sample 1), a reading frame is included in both the hit list and the longer descriptions associated with the alignments. In this example, however, the reading frame indicates the reading frame of the database sequence, not the query sequence, which is an amino acid sequence.

BIU IASI / CENTRAL UNIVERSITY LIBRARY

EXAMPLE 6: USING THE NetBLAST GRAPHICAL CLIENT PROGRAM

Here we illustrate the new NetBLAST graphical interface by repeating the search described in Example 2 but with SEG + XNU masking that makes the output more similar to that of Example 3. Figure 2.5.10A shows the dialog box used to set up a search request and Figure 2.5.10B shows one view of the search results where the alignments are depicted schematically. Compare this view with the textual version of the alignments shown in Sample 2. The NetBLAST interface provides a global view of local alignments.

The various choices of databases, parameters, and options are grouped into several categories, each of which is represented by a "folder tab" across the top of the dialog box in the NetBLAST graphical client program (Fig. 2.5.10A). In this example, the Database tab has been selected. Radio buttons are used to toggle between nucleotide and protein database types and the current list of databases of the selected type is shown in the list



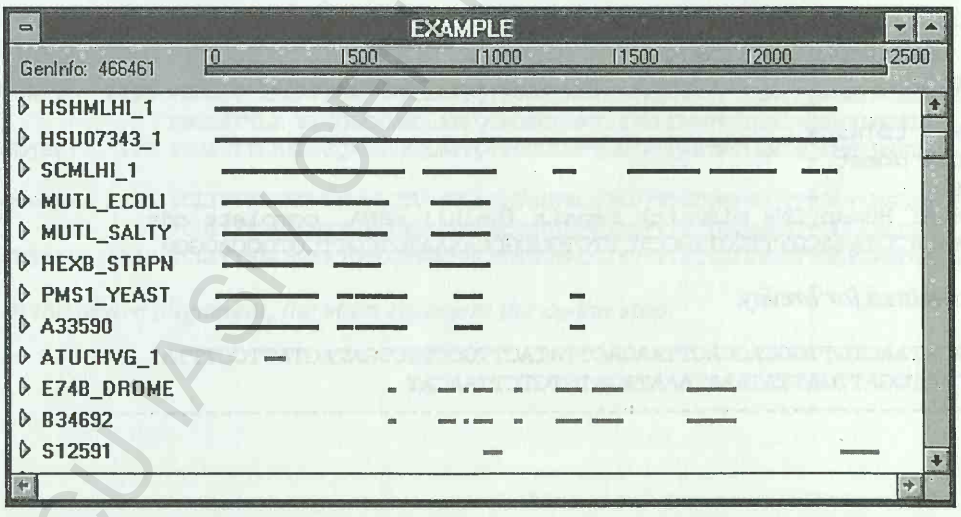


Figure 2.5.10 The NetBLAST graphical client program (see Example 4) (**A**) Dialog box. (**B**) Hit list from a BLASTX search with human MHL1 query sequence using the NetBLAST graphical client program.

FCU IASW/CENTRAL UNIVERSITY LIBRARY

box. The desired BLAST command can be determined from the type of query sequence, whether or not it is to be translated (Translate Query checkbox, which is enabled for nucleotide sequences only), and the type of database. In this example, the nucleotide query sequence is to be translated and compared to a protein database, which implies that the BLASTX command should be used, as shown in the field at the bottom of the window.

The hit list from a BLASTX search with human MLH1 query sequence using the NetBLAST graphical client program is displayed in a window (Fig. 2.5.10B). A scale across the top shows the extent of the query sequence (measured in bases in this example, because the query is a nucleotide sequence). Identifiers of protein sequences bearing similarities to the translated query are listed below, along with a graphical indication of the locations of the HSPs within the query sequence. The first two "self hits" arise from the CDS translations of the GenBank entries for the human DNA mismatch repair cDNA (two versions). The short regions at the ends of the query sequence that match nothing in these proteins are the 5′ and 3′ untranslated regions. Below the human sequences are several homologous proteins from *Saccharomyces cerevisiae* and *Escherichia coli*. The amino-terminal half of the protein is more highly conserved than the carboxy-terminal half. Alignments, sequence records, and abstracts are available by using a point-and-click interface.

EXAMPLE 7: USING TBLASTX TO SEARCH OPEN READING FRAMES DERIVED FROM CONCEPTUAL TRANSLATIONS OF A NUCLEOTIDE SEQUENCE DATABASE USING OPEN READING FRAMES DERIVED FROM A NUCLEOTIDE SEQUENCE QUERY

TBLASTX takes the six-frame translations of a nucleotide query and compares them against the six-frame translations of a nucleotide sequence database. This double translation and the comparisons require a large amount of CPU time because one TBLASTX run corresponds to 36 BLASTP runs. Therefore, TBLASTX is restricted to searches against dbEST, dbSTS, and *Alu* databases only. TBLASTX, like BLASTX and TBLASTN, is a fundamental tool for searching against dbEST (Boguski et al., 1993, 1994). For this example, we use the cDNA sequence of human MLH1 (GenBank accession number U07418), the same sequence used in Example 1.

Discussion

The results of the cDNA human hmlh1 sequence search against dbEST are shown in Sample 4. The hit list and the alignments from the first hits (dbEST-78657) are given. Two reading frames are indicated for each alignment, one for the database sequence and one for the query sequence (Frame = database/query). However, only the database sequence is listed in the hit list. In this example, the alignments correspond to four different searches using four different protein query sequences against four different protein databases. BLOSUM62 is used as the default scoring scheme but this selection can be changed easily (see manual and e-mail help files).

BU IAS/CENTRAL UNIVERSITY LIBRARY

COMMENTARY

Background Information

The earliest sequence comparison studies attempted to produce end-to-end alignments of complete sequences, also known as global alignments. This was because the sequences then available for study were those of small, globular proteins consisting of a single domain, such as cytochromes or hemoglobin subunits. Also, these alignment techniques were developed before the discovery of the exon/intron structure of genes. However, it is now recognized that most genes and proteins are modular and mosaic structures often consisting of several distinct domains and/or repeated copies of domains, the order of which may be rearranged by several genetic mechanisms (Patthy, 1991; Doolittle and Bork, 1993). Therefore, attention has shifted to algorithms for local alignment, and virtually all database search strategies in use today seek local alignments. See Altschul et al. (1994) for additional background material and references on alignment algorithms.

The classic method for finding optimal local alignments was developed by Smith and Waterman (1981). Given the large sizes of sequence databases today, it is impractical to use this algorithm except on special massively parallel computers (Brutlag, 1993). MPsrch is one such parallel Smith-Waterman implementation that is available via a public e-mail server called Blitz (contact netserv@ebi.ac.uk for more information). MPsrch is also available commercially from Intelligenetics. In addition to being slow to compute, another drawback of this algorithm is that no rigorous theory is available to evaluate the statistical significance of the gapped alignments produced (Altschul et al., 1994).

"Heuristic," as opposed to "optimal," database search methods are obtained by implementing certain shortcuts—for example, forbidding the introduction of gaps (insertion/deletion mutations) in local alignments, at least during the initial phase of the search. Although in principle heuristic methods may be less sensitive for detecting weak similarities, they are much faster when run on general-purpose computers. The two most popular heuristic search programs in use today are FASTA (Pearson and Lipman, 1988; Pearson, 1990) and BLAST (Altschul et al., 1990). The following discussion focuses on BLAST, beginning by comparing and contrasting it to FASTA.

The similarity in approach between FASTA and BLAST lies in their initial steps—both programs begin by identifying ungapped aligned segments, although they use different heuristics. In this regard, specific implementations of the BLAST programs provide the most leeway in adjusting the speed of the search, albeit at the expense of sensitivity at higher speeds. The biggest difference between the two approaches arises in what the programs do with this initial alignment information. FASTA picks the highest-scoring, ungapped aligned segment it has found and performs a local (Smith-Waterman) alignment confined within a narrow window centered about that segment. Gaps may be introduced in generating the optimized alignment. FASTA then ranks the database sequences by these optimized scores. Statistical significance of FASTA and Smith-Waterman scores is often estimated by relating individual scores to the mean and standard deviation of the scores obtained from the entire database search. However, assuming a Gaussian distribution greatly overestimates the significance (i.e., underestimates the probability) of these optimized alignment scores. Optimized scores tend to follow an extreme-value distribution which falls off by e^{-x}, where x is proportional to the alignment score, rather than the rapid e^{-x^2} decay of a Gaussian distribution.

In contrast, once the BLAST programs have found some aligned segments (using the BLAST algorithm), the segments are considered in their totality for their statistical significance. For example, two regions of similarity that are moderately to widely

BOSTON UNIVERSITY LIBRARY

separated from one another (e.g., two conserved domains separated by variable-length intervening regions having little or no discernible similarity) will be considered together by the BLAST programs and may be found to achieve statistical significance, whereas an optimized gapped alignment centered around any one of the two regions might not yield a statistically significant score.

The limitation of using ungapped alignments in BLAST programs has the benefit of making estimation of their statistical significance a tractable problem. For this purpose, Karlin-Altschul (K-A) statistics are used (Karlin and Altschul, 1990, 1993). K-A statistics afford a rapid, analytical solution to the statistics problem and are often quite accurate. With more accurate statistical significance estimates, it is possible to set a more stringent threshold for reporting database matches, thus reducing the number of random matches that must be manually considered and probably rejected. It must be noted that this is an absolute necessity for high-throughput sequencing projects that must manage data at rates of 1 megabase or more per week.

With real-world sequence data (not random models of sequence data), K-A statistics tend to fall down most frequently and most dramatically when two sequences being compared contain regions of statistically biased residue composition (e.g., simple sequence repeats or SSRs). To address this problem, the BLAST family of programs support a "filter" (filter) option to have these compositionally biased regions masked from the query sequence prior to searching. The principles and practice of sequence masking are discussed in more detail below.

The BLASTN program for comparing a nucleotide query sequence against a nucleotide database is insensitive at identifying even moderately distant homologs and is not intended to be used for this purpose. FASTA is far better at this application, but not nearly so fast as BLASTN. Most of these differences in speed and sensitivity arise from BLASTN's current restriction to using a word length (see BLAST Search Algorithm) of 12, while FASTA can use a word length (or "ktup") of length 1 to 6. What this means is that there must be at least twelve consecutive matching nucleotides for BLASTN to key in on a similar segment, whereas FASTA needs as little as one matching nucleotide. The larger this initial word length, the faster each program runs, but the sensitivity suffers at the same time.

With BLASTN, however, the sensitivity problem is often not an issue because better sensitivity in identifying similarity between coding regions can be obtained by comparing the translation products rather than the encoded nucleotide sequences (see Examples and States et al., 1991). This arises from the redundancy of the genetic code, the small size of the DNA alphabet compared with that of proteins, and the fact that it is possible to take advantage of positively scoring imperfect matches (conservative amino acid substitutions) for proteins but not nucleic acids. In searching for similarity between nucleotide regulatory regions, however, FASTA remains superior.

Some final distinctions between BLAST and FASTA include the following: BLASTN, BLASTX, TBLASTN, and TBLASTX compare both strands of the query by default, whereas some implementations of FASTA do not; for protein-protein comparisons using default parameter values, BLASTP rivals or exceeds FASTA in sensitivity and specificity and runs considerably faster; there is no functional equivalent in FASTA to BLASTX, TBLASTN, or TBLASTX; FASTA runs on more computers than BLAST; and FASTA reads more database formats than do the BLAST programs. This last apparent advantage is nullified by the availability of comprehensive nonredundant databases that are updated daily and available for searching by BLAST e-mail or network services. FASTA e-mail

servers are supported at a number of sites (see *UNIT 2.4*). FASTA source code is available from Dr. William Pearson by anonymous FTP (see *UNIT 2.4*).

Scoring Systems and Alignment Statistics

In order to rank the results of a database search, it is necessary to have some way to calculate the quality of each individual alignment. This is done using a scoring system, which normally consists of a table of residue substitution scores and rules for its use in calculating an alignment score. The default scoring systems used by the BLAST family of programs are BLOSUM62 (Henikoff and Henikoff, 1992) when comparing proteins and a simple unitary matrix when comparing nucleotide sequences. Although these scores work well in typical cases, there may be reasons to select an alternate scoring system using the M= (command-line) or MATRIX (e-mail) options (more than 65 different matrices are available). Scores that are best for detecting distantly related sequences differ from those suited to finding nearly identical short motifs (Altschul, 1991, 1993). Special scoring systems have also been developed for detecting frameshift sequencing errors (Claverie, 1993). The latest version of BLAST (version 1.4) supports a multiple matrix option.

The BLAST search algorithm seeks a type of local alignment called a high-scoring segment pair (HSP). An HSP is a pair of sequence segments, one drawn from the query sequence and the other from the database sequence, that may be aligned without gaps to achieve a high score. Calculation of the score of an HSP is a simple matter of summing the individual substitution scores for each aligned pair of letters. The end points of an HSP are chosen such that the score is locally maximal. In order to be reported by BLAST, the score must meet or exceed a score threshold (S). It is possible to specify the value of S as an input parameter.

Given an alignment reported by a database search, an important question is whether it represents a true relationship or is due simply to chance. Given certain characteristics of the query sequence, the database, and the scoring system, mathematical analysis can be used to calculate a probability density function for the distribution of HSP scores resulting from a database search (Karlin and Altschul, 1990). To see if a particular database hit should be considered significant, simply compare its HSP score to this distribution. More precisely, calculate a p value, which gives the probability that an HSP with a score as good as the one observed could be due simply to chance.

Because the HSP score that must be achieved to be considered significant depends on certain aspects of the search context, especially the scoring system, it is difficult to know the appropriate value of S to use in a search. For this reason, it is more convenient to specify the sensitivity of the search in terms of the significance threshold (E), which takes the search context into account. The E parameter may be thought of as the number of matches expected to be observed by chance alone during the database search. Given the statistical model of Karlin and Altschul, the values of E and S are interconvertible—based only on knowledge of the scoring system, the length and composition of the query sequence, and the size and hypothetical composition of the database.

BLAST Search Algorithm

Having defined what is needed in a database search, the next question is how to perform the search for HSPs in a reasonable period of time. When comparing two sequences of length N, an exhaustive search for HSPs would require time proportional to N^2. Such a time requirement would be prohibitive when searching a sequence database containing hundreds of thousands of sequences. To get around this problem, many rapid search algorithms make use of word-based methods. Imagine that the residues in the query sequence are taken several at a time instead of singly. These groups of letters are known

BIOLIST CITRA UNIVERSITY LIBRARY

as words and the number of letters is called the word size (W). Related sequences are likely to share many common words, whereas unrelated sequences will have fewer. By limiting the search for similarities to only the regions near matching words, the search space that must be examined is dramatically reduced, leading to faster search times. The time required for the search is still proportional to N^2, but the proportionality constant is small.

Although the use of word-based methods can lead to faster search times, these algorithms are heuristic rather than rigorous and there is some chance that weaker, yet still statistically significant similarities may be missed. This is because the sequences may have diverged to the point where no common words of length W remain. This tradeoff between speed and sensitivity is affected by the value chosen for W. Larger W leads to faster searches while sacrificing sensitivity. On the other hand, smaller W leads to slower but more thorough searches.

Most word-based methods require exact matching of the letters within the word. Unfortunately, under these conditions obtaining satisfactory sensitivity may require reducing W to such a small value (perhaps 2, or even 1) that the speed advantage afforded by using a word-based method is nearly negated. BLAST introduces a novel method to deal effectively with this problem. Essentially, the same score matrix used to calculate the quality of an HSP is applied to the generation of words from the query sequence. For each word in the query, a list of all words that would produce a score of at least T using the score matrix is compiled. This extended group of words is called the neighborhood and T is the neighborhood score threshold. The concept of neighborhood words is illustrated in Figure 2.5.11. The value of T, like that of W, affects the speed and sensitivity of the search. Increasing the value of T results in faster searches because there will be fewer neighborhood words to check for in the database sequence.

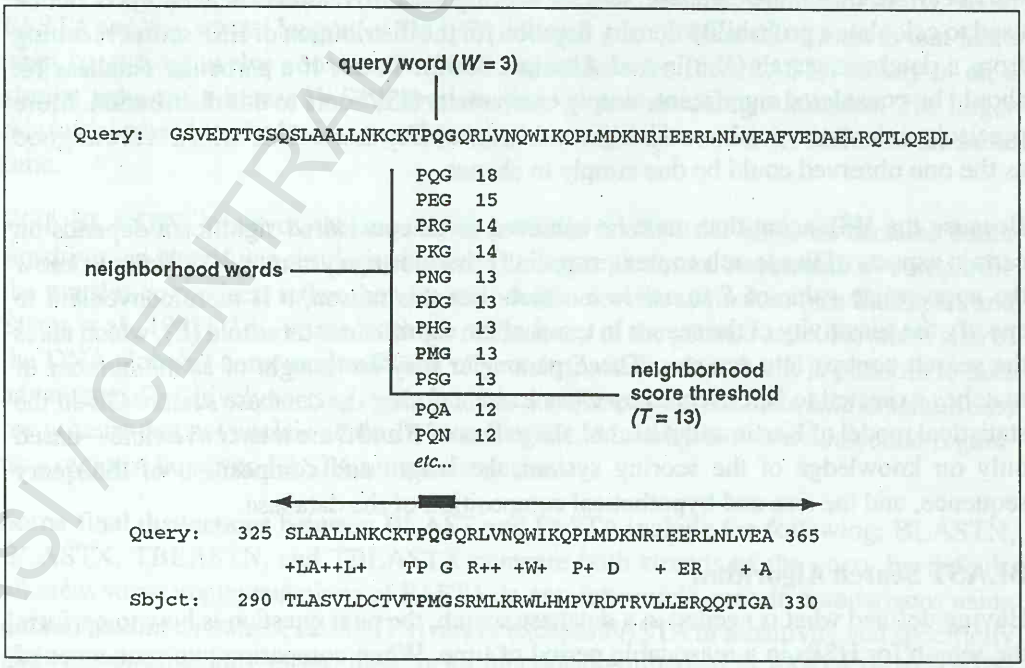

Figure 2.5.11 Neighborhood words used by the BLAST search algorithm. The BLAST search algorithm uses a word-based (or hashing) scheme to improve speed, but uses neighborhood words to preserve sensitivity. Shown here is an example of the neighborhood word list generated for a single word (PQG or Pro-Gln-Gly) in the query sequence using $W = 3$ and $T = 13$. Once a word match is encountered between the query and a database sequence, an attempt is made to extend the match in both directions to achieve a locally maximal score, the HSP score.

BU IASI / CENTRAL UNIVERSITY LIBRARY

Once the neighborhood words have been tabulated for the query sequence, each sequence in the database is scanned for the presence of matching words. For each word hit found in this way, an attempt is made to extend the match to the left and to the right (Fig. 2.5.8) to see if an HSP having a score of at least *S* can be identified. A typical approach is to continue extension until the cumulative score reaches zero and then take the point at which the maximum value of the cumulative score was achieved as the end of the run. However, BLAST introduces an additional heuristic in which the extension can also be terminated if the cumulative score drops off by some value *X* or more. For typical values of *X*, this speeds up the search without appreciably affecting the results. Reducing *X* will lead to further performance enhancement, but could result in missing some significant similarities. Increasing *X* to some very large value will ensure that no hits are missed as a result of premature hit termination.

Low-Complexity Sequences

The statistical framework upon which BLAST is based assumes that proteins can be modeled as random sequences. However, many real proteins contain patches of distinctly nonrandom sequence. These patches may be homopolymeric tracts, short-period repeats, or merely regions enriched in one or a few amino acids. Such low-complexity (LC) sequences are surprisingly abundant in real proteins; it has been observed that at least 25% of proteins in the database contain at least one LC region (Wootton, 1994a,b). Very little is known about the structure, function, or evolution of LC segments.

Despite the fact that LC sequences may well have interesting properties and functions, they wreak havoc on database searches. This is primarily because the residue frequencies within such regions differ markedly from the database as a whole. The result is that pairs of proteins containing LC sequences rich in the same amino acids may be aligned with each other to achieve high scores even though other regions of the proteins are entirely dissimilar. Because these alignments do not reflect a common ancestry, no functional inference is justified despite their high statistical significance. Even a small LC segment in a query sequence (e.g., see Example 3) can generate a multitude of these uninteresting hits, making the output difficult to interpret if not outright unmanageable. In some cases, the high volume of LC hits can completely swamp potentially interesting matches to distantly related proteins.

Two approaches have been devised to locate LC regions in query sequences. The SEG program (Wootton and Federhen, 1993) uses a rigorous mathematical definition of complexity and optimally segments a sequence into regions of alternating high and low complexity (Fig. 2.5.12). The XNU program (Claverie and States, 1993) specifically seeks short-period repeats by looking for runs of high score when the sequence is offset by short distances and compared to itself. The two methods are complementary: each can identify regions not found by the other, although the overall results are similar. Both programs support a mode of operation in which the sequence is written back out with the residues of the identified segments converted to Xs (an ambiguity code that means "any residue"). The strategy of "X-ing out" specific regions of the query sequence prior to a database search is known as "masking" or "filtering." For the BLASTP, BLASTX, and TBLASTX programs, the -filter command-line option (or the FILTER e-mail directive) followed by seg, xnu, or seg + xnu can be used to instruct the program to perform automatic masking on the query sequence using the algorithms separately or in combination.

BCU INFORMATION SERVICES CENTRAL UNIVERSITY LIBRARY

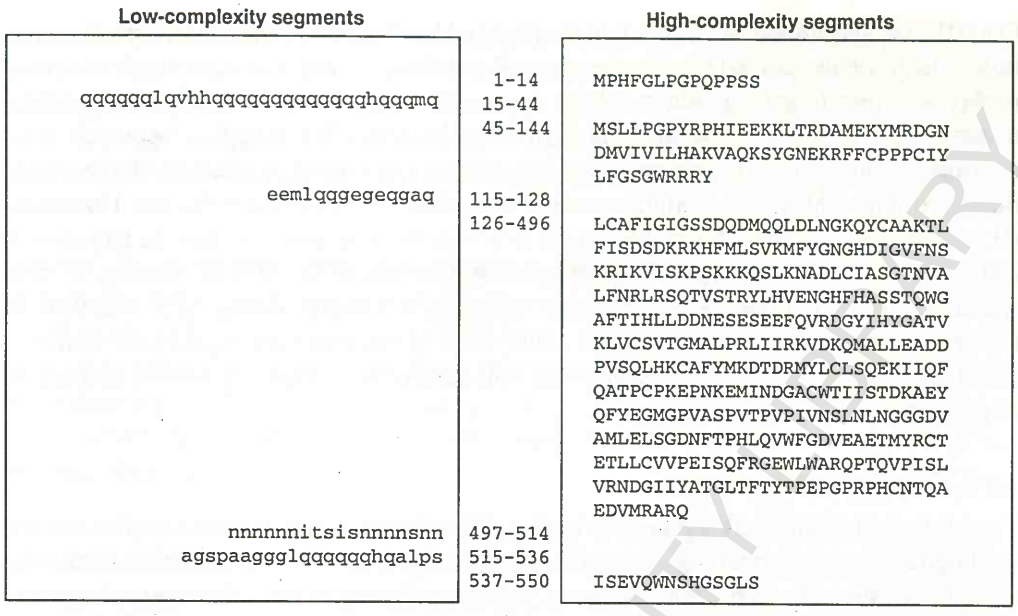

Figure 2.5.12 Low-complexity segments reported by the seg program. Subjecting the fruit fly RBP-J_κ sequence to analysis by seg produces the output shown here, in which the low-complexity segments are printed on the left in lower case and the high-complexity segments on the right in upper case. When this sequence is used as a query for a BLASTP search using the seg filter option, the letters of the low-complexity segments are converted to Xs prior to performing the database search.

STRATEGIES AND TIPS

Screening for Query Contamination

Imagine the frustrating results of screening a clone library with a probe that has been contaminated with cloning vector sequences. Or suppose that a probe used to hybridize against human genomic DNA contains a portion of an *Alu* repetitive element. Just as when performing a hybridization experiment, the quality of the query sequence that is used to "probe" for homology against a sequence database is critical to obtaining meaningful BLAST results. A newly-generated sequence that has been subjected to relatively little scrutiny may well be contaminated with vector sequences. Other sorts of contamination, for example with mitochondrial or bacterial sequences, are also possible. In addition, the presence of repetitive elements or structural RNA genes represents a sort of natural "contamination." In all of these cases, many hits will be produced that have a high statistical significance, but they will be frustrating and minimally informative, and may obscure more subtle but interesting homologies.

In some cases, the problem of query contamination can be difficult to recognize. Based on the analogy between database searching and molecular hybridization, it might be expected that a query sequence containing a repetitive element would generate extremely high numbers of matches, many of which would look essentially alike. The copy numbers for repetitive elements in sequence databases, however, are far smaller than in genomes, so the volume of search output may not be so high as to cause alarm. Furthermore, many of the copies that do exist are small portions of other gene sequences, and their presence is rarely mentioned in the definition lines in the hit list or alignment section. They may not even be annotated in the full database record describing a sequence. However, one thing to watch for when searching GenBank and Swiss-Prot is definition lines for any of several representative *Alu* repeat sequences that have been included as "warning entries." These warning entries are:

RAJIV GANDHI UNIVERSITY LIBRARY

GenBank:

U14570 ***ALU WARNING: Human Alu-Sb2 subfamily consensus sequence
U14571 ***ALU WARNING: Human Alu-Sc subfamily consensus sequence
U14572 ***ALU WARNING: Human Alu-Sp subfamily consensus sequence
U14573 ***ALU WARNING: Human Alu-Sq subfamily consensus sequence
U14574 ***ALU WARNING: Human Alu-Sx subfamily consensus sequence
```

Swiss-Prot:

```
P23959|ALUA_HUMAN !!!! ALU CLASS A WARNING ENTRY !!!!
P23960|ALUB_HUMAN !!!! ALU CLASS B WARNING ENTRY !!!!
P23961|ALUC_HUMAN !!!! ALU CLASS C WARNING ENTRY !!!!
P23962|ALUD_HUMAN !!!! ALU CLASS D WARNING ENTRY !!!!
P23963|ALUE_HUMAN !!!! ALU CLASS E WARNING ENTRY !!!!
P23964|ALUF_HUMAN !!!! ALU CLASS F WARNING ENTRY !!!!
```

It is preferable to detect query contamination by explicit test rather than chance discovery. One way to do this is to perform preliminary BLAST searches against special sequence databases containing various classes of problematic sequences. For example, the BLAST server provides access to: (1) a vector database which contains nucleotide sequences of a number of standard cloning vectors; (2) the alu amino acid sequence database which contains six-frame translations of representative human *Alu* repeats; and (3) the alu nucleotide sequence database which contains representative *Alu* elements (Jurka et al., 1992; Claverie and Makalowski, 1994). Preliminary screening of all new sequences for possible contamination is highly advisable.

Masking Low-Complexity Subsequences

As discussed in the section on Low-Complexity Sequences and illustrated in Example 3, the filter option in BLAST can be used along with seg, xnu, or seg + xnu commands to instruct the program to detect LC sequences in the query and exclude them from the search. Use of this option is highly recommended for all database searches that involve comparisons at the amino acid level. To illustrate the effect that LC masking can have on a database search, consider a BLASTP search using the translated product of the fruit fly RBP-J_κ gene (Furukawa et al., 1991) as the query sequence. The normal function of this gene is to encode a protein that specifically binds to the immunoglobulin J_κ recombination signal sequence.

When the RBP-J_κ sequence is used in a BLASTP search of the the nonredundant database without LC masking, 898 sequences are found to contain at least one HSP (by default only the best 250 are reported). The hit list from this search is shown in Figure 2.5.13. Several "self hits" involving other RBP-J_κ sequences in the database are observed (marked by a square in Fig. 2.5.13), followed by many weaker matches that are reported to be statistically significant. Many of the remaining sequences are false positives whose similarity is merely due to the fact that the segments contain unusually high proportions of glutamine (Q) and asparagine (N; see Fig. 2.5.12). With so many false positives, it is tempting to abandon further examination of the results, but a look at the 516th sequence in the list (marked by a star in Figs. 2.5.13 and 2.5.14) reveals an interesting similarity to the human fork head–related protein (Hromas et al, 1993). The alignment consists of a single high-scoring segment, shown in Figure 2.5.14, that does not fall within a low-complexity region of RBP-J_κ.

Figure 2.5.13 Hit list from a BLASTP search of the fruit fly RBP-J_κ protein with no filtering. "Self hits" (marked by squares) correspond to other RBP-J_κ sequences present in the database. The sequence of the fork head–related protein is marked by a star.

Repeating the search with the same query and database, but with the addition of the filter seg + xnu option produces a much smaller hit list: 26 sequences containing one or more HSPs. The results are shown in Figure 2.5.14. The first eight hits are J_κ sequences (marked by squares in Figs. 2.5.13 and 2.5.14), followed by the fork head–related protein. Many of the false positives have disappeared as a result of the masking, allowing the fork head–related protein to improve its standing to ninth on the list. This example illustrates the necessity to use the seg + xnu filter systematically in protein similarity search.

CHAPTER 3
Detection and Assay Methods

INTRODUCTION

The success or failure of protein-centered projects can frequently be traced to the quality of the analytical procedures used to characterize the sample at different stages. Qualitative and quantitative analysis can aid in definition of the sample for the purpose of designing separations. A knowledge of the properties of the desired protein (e.g., whether it has a high aromatic amino acid content) can suggest methods of analysis that will help locate the desired protein in a complex mixture. Establishing the properties of an isolated protein creates benchmarks that future researchers can use to evaluate their protocols and final product. Accurate quantitation of the amount of protein at the beginning, middle, and end of a series of steps is the only valid way to evaluate the overall yield of a procedure. The observation of significant loss of protein following a particular purification procedure, without a substantial increase in the purity of the desired protein, would indicate that the procedure should be omitted or revised.

Several spectroscopic procedures for characterizing protein samples are described in *UNIT 3.1*. Measuring the absorbance of the aromatic amino acids in a protein at different wavelengths yields a very useful measure of protein concentration. This is nondestructive and requires very little sample or time. A more qualitative, but much more sensitive, evaluation is provided by fluorescence spectroscopy.

Another approach is amino acid analysis—qualitative analysis, to determine purity, and quantitative analysis, to provide concentrations—both of which are presented in *UNIT 3.2*. Procedures are also given for calculating amino acid ratios from primary analytical data. Significant advances that have improved the precision and sensitivity of amino acid analysis have reinvigorated this method, which had for some years been neglected.

A common method for enhancing the sensitivity of protein detection is to radiolabel the proteins, as detailed in *UNIT 3.3*. This approach may also be employed to help quantitate the binding of peptide to other molecules or for radioimmunoassays. Several procedures for iodination (introduction of ^{125}I or ^{131}I) are presented; the choice between them will depend on the sample type, the content of residues sensitive to oxidation, and the amino acids that are critical to function. Procedures for handling radioactive samples, for separating labeled from unlabeled peptides, and for iodination to equimolar or higher levels (using a mixture of radioactive and nonradioactive iodine isotopes) are also provided. When Tyr or His residues are absent, or cannot be iodinated because they are critical for function, alternative methods involving the incorporation of ^{14}C or ^{3}H may be employed instead. The methods described include labeling by acetylation at amino groups on lysine or at the amino terminus using the Bolton-Hunter reagent or acetic anhydride, by reductive alkylation, and by labeling at Lys residues with iodoacetic acid or iodoacetamide. Two synthetic methods, reduction of a peptide containing iodo-Tyr residues and incorporation of labeled amino acids, are also presented.

Measurement of the total protein content of a sample is discussed in *UNIT 3.4*. Three methods based on reduction of Cu^{2+} to Cu^{+} followed by chelation of the cuprous ion by various reagents (biuret, Hartree-Lowry, and bicinchinonic acid) are presented. In addition, a quantitative measure of total protein based on protein hydrolysis and the ninhydrin

BOWMAN GENERAL UNIVERSITY LIBRARY

reaction is described. The use of UV absorption, Coomassie dye binding, and weight analysis to determine protein content complete the presentation. Important considerations for performing these assays, such as dealing with interfering substances, are detailed throughout the unit.

Some aspects involved in the design of enzyme assays are discussed in *UNIT 3.5*. Parameters that affect both enzyme and substrate are evaluated and suggestions to optimize the quantitation of enzymatic activity are enumerated. The proper concentration range for conducting initial velocity measurements is presented, and different methods of data presentation and analysis are discussed.

Tagging a protein with a group that permits facile detection is an excellent way, for example, to study the movement of a protein through internalization or compartmentalization. A variety of reagents are available for attaching biotin to functional groups or the surface of a protein (*UNIT 3.6*). Detection and localization can be achieved by the strong and specific binding of avidin or streptavidin. These reactions can also be used to label proteins at cell surfaces.

Additional procedures to quantitate total protein content by biological activity by analytical assay methods will be presented in future updates to this chapter.

Spectrophotometric Determination of Protein Concentration

This unit describes spectrophotometric methods for measuring the concentration of a sample protein in solution. In Basic Protocol 1, absorbance measured at 280 nm (A_{280}) is used to calculate protein concentration by comparison with a standard curve or published absorptivity values for that protein (a_{280}). In the Alternate Protocol, absorbance measured at 205 nm (A_{205}) is used to calculate the protein concentration. The A_{280} and A_{205} methods can be used to quantitate total protein in crude lysates and purified or partially purified protein. Both of these methods are simple and can be completed quickly. The A_{280} method is the most commonly used. The A_{205} method can detect lower concentrations of protein and is useful for dilute protein samples, but is more susceptible to interference by reagents in the protein sample than the A_{280} method. Basic Protocol 2 uses a spectrofluorometer or a filter fluorometer to measure the intrinsic fluorescence emission of a sample solution; this value is compared with the emissions from standard solutions to determine the sample concentration. The fluorescence emission method is used to quantitate purified protein. This simple method is useful for dilute protein samples and can be completed in a short amount of time.

USING A_{280} TO DETERMINE PROTEIN CONCENTRATION

BASIC PROTOCOL 1

Determination of protein concentration by measuring absorbance at 280 nm (A_{280}) is based on the absorbance of UV light by aromatic amino acids in protein solutions—due primarily to tryptophan and tyrosine residues and to a lesser extent phenylalanine residues. The measured absorbance of a protein sample solution is used to calculate the concentration either from its published absorptivity at 280 nm (a_{280}) or by comparison with a calibration curve prepared from measurements with standard protein solutions. This assay can be used to quantitate solutions with protein concentrations of 20 to 3000 µg/ml.

Materials

3 mg/ml standard protein solution (see recipe; optional)
Sample protein
Spectrophotometer with UV lamp

1. For calibrating with standards, use the 3 mg/ml standard protein solution to prepare dilutions of 20, 50, 100, 250, 500, 1000, 2000, and 3000 µg/ml in the same solvent as used to prepare the sample protein. Prepare a blank consisting of solvent alone.

   Ideally, for purified or partially purified protein, the protein standard should have an aromatic amino acid content similar to that of the sample protein. For the total protein of a crude lysate, bovine serum albumin (BSA) is a commonly used standard for spectrophotometric quantitation of protein concentration. A 3 mg/ml solution of BSA should have an A_{280} of 1.98, based on an A_{280} of 6.61 for a 1% (w/v) solution.

2. Turn on the UV lamp of the spectrophotometer and set the wavelength to 280 nm. Allow the instrument to warm up 30 min before taking measurements.

3. Zero the spectrophotometer with the solvent blank.

4. Measure the absorbance of the protein standard and unknown solutions.

   If the A_{280} of the sample protein is >2.0, dilute the sample further in the same solvent and measure the A_{280} again.

Copyright © 1996 by John Wiley & Sons, Inc.

BOSTON CENTRAL UNIVERSITY LIBRARY

5a. *If the a_{280} of the protein is known:* Calculate the unknown sample concentration from its absorbance value using Equation 3.1.1.

In this equation a_{280} has units of ml/mg cm and b is the path length in cm.

$$\text{concentration (mg/ml)} = \frac{A_{280}}{a_{280} \times b}$$

Equation 3.1.1

5b. *If standard solutions are used for quantitation:* Create a calibration curve by either plotting or performing regression analysis of the A_{280} versus concentration of the standards. Use the absorbance of the sample protein to determine the concentration from the calibration curve.

ALTERNATE PROTOCOL

USING A_{205} TO DETERMINE PROTEIN CONCENTRATION

Determination of protein concentration by measurement of absorbance at 205 nm (A_{205}) is based on absorbance by the peptide bond. The concentration of a protein sample is determined from the measured absorbance and the absorptivity at 205 nm (a_{205}). This assay can be used to quantitate protein solutions with concentrations of 1 to 100 µg/ml protein.

Additional Materials (also see Basic Protocol 1)

Brij 35 solution: 0.01% (v/v) Brij 35 (Sigma) in an aqueous solution appropriate for dissolving or diluting the sample protein

1. Dissolve or dilute the protein sample in Brij 35 solution.
2. Turn on the UV lamp of the spectrophotometer and set the wavelength to 205 nm. Allow the instrument to warm up 30 min before taking measurements.
3. Zero the spectrophotometer with the Brij 35 solution alone.
4. Measure the absorbance of the sample protein.

5a. *If the a_{205} of the protein is known:* Use Equation 3.1.1 to calculate the concentration of the sample protein *except* substitute the appropriate values for A_{205} and a_{205}.

5b. *If the a_{205} is not known:* Estimate the concentration of the sample protein from its measured absorbance using Equation 3.1.2.

$$\text{concentration (mg/ml)} = \frac{A_{205}}{31 \times b}$$

Equation 3.1.2

In this equation, the absorptivity value, 31, has units of ml/mg cm and b is the path length in cm.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

USING FLUORESCENCE EMISSION TO DETERMINE PROTEIN CONCENTRATION

Protein concentration can also be determined by measuring the intrinsic fluorescence based on fluorescence emission by the aromatic amino acids tryptophan, tyrosine, and/or phenylalanine. Usually tryptophan fluorescence is measured. The fluorescence intensity of the protein sample solution is measured and the concentration calculated from a calibration curve based on the fluorescence emission of standard solutions prepared from the purified protein. This assay can be used to quantitate protein solutions with concentrations of 5 to 50 μg/ml.

Materials

Protein standard solution prepared using the purified protein (see recipe)
Sample protein
Spectrofluorometer *or* filter fluorometer with an excitation cutoff filter ≤285 nm and an emission filter >320 nm

1. Prepare dilutions of the purified protein at 5, 7.5, 10, 25, and 50 μg/ml in the same solvent as the sample protein. Prepare a blank consisting of solvent alone.
2. Turn on the lamp of the instrument and allow it to warm up 30 min before taking measurements.

   If a spectrofluorometer is used, set the excitation wavelength to 280 nm and the emission wavelength to between 320 and 350 nm. If the exact emission wavelength is not known, determine it empirically by scanning the standard solution with the excitation wavelength set to 280 nm. If the instrument is a filter fluorometer, use an excitation cutoff filter ≤285 nm and an emission filter >320 nm.
3. Zero the instrument with the solvent blank.
4. Measure the fluorescence of the protein standard and sample protein solutions.
5. Create a calibration curve by either plotting or performing regression analysis of the fluorescence intensity versus concentration of the standards. Using the fluorescence intensity of the sample protein, determine the concentration from the calibration curve.

   Fluorescence emission is a linear function of concentration only over a limited range.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Standard protein solution, 3 mg/ml

Weigh out dry protein and prepare a stock solution at a concentration of 3 mg/ml in the same solvent as used for the sample protein. Store up to 3 months at –20°C.

To prepare calibration standard solutions, dilute the stock solution in solvent to give the desired final concentrations for the standard curve.

Bovine serum albumin (BSA, fraction V; Sigma) is frequently used for a protein standard solution. A 3 mg/ml solution of BSA should have an A_{280} of 1.98, based on an A_{280} of 6.61 for a 1% (w/v) solution.

For quantitation of a purified or partially purified protein, if possible, the protein standard should have an aromatic amino acid content similar to that of the sample protein.

BOULDER CENTRAL UNIVERSITY LIBRARY

COMMENTARY

Background Information

Measuring absorbance at 280 nm (A_{280}) is one of the oldest methods for determining protein concentration (Warburg and Christian, 1942; Layne, 1957). This method is still widely used because it is simple and does not require incubating the sample with exogenous chromophores. However, the detection limit is higher than colorimetric methods and therefore higher concentrations of protein are necessary. The A_{280} method requires that the protein being quantitated have aromatic amino acids, primarily tryptophan. Because of the variability in aromatic amino acid content among different proteins, their absorptivity at 280 nm (a_{280}) also varies. Therefore, if calibration standards are used for quantitation, the aromatic amino acid content of the standard must be similar to that of the sample protein for accurate results. Accordingly, the quantitation of proteins by peptide bond absorption at 205 nm (A_{205}) is more universally applicable among proteins. Furthermore, the absorptivity for a given protein at 205 nm is several-fold greater than that at 280 nm (Scopes, 1974; Stoscheck, 1990). Thus lower concentrations of protein can be quantitated with the A_{205} method. The disadvantage of this method is that some buffers and other components absorb at 205 nm (Stoscheck, 1990).

In addition to the aromatic amino acids, several others have absorption maxima in the UV range. Table 3.1.1 shows the wavelengths of absorption maxima and corresponding molar absorptivity (ε) for the amino acids with appreciable absorbance in the UV range. Only tryptophan has an absorption maximum at 280 nm, although tyrosine will absorb somewhat at that wavelength. The ε_{280} for tryptophan is nearly five-fold greater than that for tyrosine (Table 3.1.2). Several amino acids other than those in Table 3.1.1 absorb light below 205 nm (Fasman, 1989), but either the molar absorptivities are too low to be significant or the wavelengths are too short for practical absorbance measurements.

The aromatic amino acids also have fluorescence emissions when excited by light in the UV range. Table 3.1.3 gives the excitation wavelength, fluorescence emission wavelength, and quantum yield (Q) for tryptophan, tyrosine, and phenylalanine. The quantum yield is the ratio of photons emitted to photons absorbed. Typically, phenylalanine fluorescence is not detected in the presence of tyrosine and tryptophan due to low Q. Furthermore, tyrosine fluorescence is nearly completely quenched if the tyrosine residue is ionized or near an amino group, a carboxyl group, or a tryptophan residue (Teale, 1960; Freifelder, 1982). Therefore, tryptophan fluorescence is what is customarily measured.

Measurement of intrinsic fluorescence by aromatic amino acids is primarily used to obtain qualitative information (Freifelder, 1982). However, with a protein standard whose aromatic amino acid content is similar to that of the sample, intrinsic fluorescence can be used for quantitation (Hawkins and Honigs, 1987). An additional consideration is that the tertiary

Table 3.1.1 Absorption Maxima and Molar Absorptivity (ε) of Amino Acids[a]

Amino acid	Wavelength maxima (nm)	$\varepsilon \times 10^{-3}$ (l/mol cm)

structure of a protein will influence the fluorescence, e.g., adjacent protonated acidic groups in a protein molecule will quench tryptophan fluorescence (Freifelder, 1982).

Critical Parameters and Troubleshooting

A 1-cm path length quartz cuvette is most often used to make absorbance measurements. However, quartz cuvettes with shorter path lengths, 0.01 to 0.5 cm, are available (e.g., from Hellma Cells or Beckman); these shorter path length cuvettes allow higher concentrations of protein solutions to be measured. Equation 3.1.1 and Equation 3.1.2 assume the cuvette has a path length of 1 cm; when cuvettes of shorter path length are used, the correct value for b must be substituted in the equation.

The solvent pH and polarity will affect the absorbance and fluorescence properties of a protein. A notable example of pH effects on absorbance is seen with tyrosine residues, where a change in pH from neutral to alkaline results in a shift of the absorbance maximum to a longer wavelength and an increase in absorptivity due to dissociation of the tyrosine phenolic hydroxyl group (Freifelder, 1982; Fasman, 1989). An example of solvent polarity effects on fluorescence is observed with tryptophan, where a decrease in solvent polarity results in a shift in fluorescence emission to shorter wavelengths and an increase in intensity (Freifelder, 1982). Because of these effects, the following precautions should be taken for accurate results: (1) when calibration curves are used for quantitation by absorbance or fluorescence, standards must be in the same solvent as the samples; and (2) when a published absorptivity at a given wavelength is used for quantitation, the solvent composition of the sample must be the same as that used in obtaining the published data.

Many buffers and other reagents can interfere with A_{280} and A_{205} spectrophotometric measurements. Stoscheck (1990) lists the concentration limits for many such reagents used in these spectrophotometric methods. The more commonly used reagents that absorb at 280 and 205 nm are listed in Table 3.1.4. In addition, reagents that contain carbon-carbon or carbon-oxygen double bonds can interfere with the A_{205} method.

Because stray light can affect the linearity of absorbance versus concentration, absorbance values >2.0 should not be used for sample proteins measured by the A_{280} or A_{205} method. Samples with absorbance >2.0 should be diluted further in the appropriate buffer to obtain absorbances <2.0.

Nucleic acids have substantial absorbance at 280 nm and can interfere with A_{280} quantitation of protein in crude samples. To resolve the protein concentration in such samples, measure the absorbance at 260 nm and 280 nm and calculate the protein concentration as follows (Warburg and Christian, 1942; Layne, 1957): protein concentration (mg/ml) = $1.55 \times A_{280} - 0.76 \times A_{260}$.

BOSTON UNIVERSITY CENTRAL LIBRARY

Table 3.1.4 Concentration Limits of Interfering Reagents for A_{205} and A_{280} Protein Assays[a]

Reagents[b]	A_{205}	A_{280}
Ammonium sulfate	9% (w/v)	>50% (w/v)
Brij 35	1% (v/v)	1% (v/v)
DTT	0.1 mM	3 mM
EDTA	0.2 mM	30 mM
Glycerol	5% (v/v)	40% (v/v)
KCl	50 mM	100 mM
2-ME	<10 mM	10 mM
NaCl	0.6 M	>1 M
NaOH	25 mM	>1 M
Phosphate buffer	50 mM	1 M
SDS	0.10% (w/v)	0.10% (w/v)
Sucrose	0.5 M	2 M
Tris buffer	40 mM	0.5 M
Triton X-100	<0.01% (v/v)	0.02% (v/v)
TCA	<1% (w/v)	10% (w/v)
Urea	<0.1 M	>1 M

[a]Values from Stoscheck, (1990).

[b]Abbreviations: DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; 2-ME, 2-mercaptoethanol; SDS, sodium dodecyl sulfate; TCA, trichloroacetic acid.

This estimation of protein concentration is valid up to 20% (w/v) nucleic acid or an A_{280}/A_{260} ratio <0.6.

Anticipated Results

Depending on the protein, the concentration range for the A_{280} method is 20 to 3000 µg/ml, for the A_{205} method is 1 to 100 µg/ml, and for the fluorescence emission method is 5 to 50 µg/ml.

Published absorptivities of proteins at 280 nm are usually given as the absorbance for a 1% (w/v) protein solution per cm, $A^{1\%}$, or as the molar absorptivity, ε, which has units of l/mol cm. To convert these published coefficients to units of mg/ml, use either Equation 3.1.3 or Equation 3.1.4.

$$\text{concentration (mg/ml)} = \frac{A_{280} \times 10}{A^{1\%} \times b}$$

Equation 3.1.3

Molecular weight in Equation 3.1.4 is the molecular weight of the protein.

$$\text{concentration (mg/ml)} = \frac{A_{280} \times \text{molecular weight}}{\varepsilon_{280} \times b}$$

Equation 3.1.4

Time Considerations

When the absorptivity for a protein is known, the A_{280} and A_{205} measurements require <30 min depending on the number of samples. When standards are used for quantitation with these assays or for intrinsic fluorescence quantitation, 1 hr is required.

Quantitative Amino Acid Analysis

The use of quantitative amino acid analysis in the characterization of protein samples is often overlooked in many laboratories. This was typically due to the difficulties involved in obtaining reliable amino acid composition data, as well as to the advent of colorimetric dye-binding assays as alternative methods to determine protein concentration. However, many proteins do not bind dyes in the same way as the proteins normally used as standards, making quantitation by those techniques difficult. Fortunately, at many institutions, the creation of protein chemistry core laboratories devoted mainly to protein sequence analysis and peptide synthesis has provided new instrumentation that yields the necessary precision. This unit describes the information that can be derived from quantitative amino acid analysis, presents some details on sample preparation, and gives examples of the calculations that are needed.

INFORMATION OBTAINED FROM AMINO ACID ANALYSIS

The benefits of amino acid composition data are two-fold. First, identifying the nature of the amino acids present in a sample can provide an important qualitative measure of the purity of the preparation. Amino acid analysis does not depend on the shape, charge, or function of a protein because the hydrolysis completely destroys structure and reduces the protein to its constituent amino acids. Although large proteins typically contain a mixture of all the commonly occurring amino acids, certain residues are relatively rare—Trp, Met, His, Cys, and occasionally Arg are present at lower than average ratios compared to Gly, Ala, Ser, and Leu. For a pure protein, the ratios of the amino acids should approach the theoretical levels to within ~10%, with a few caveats. For a sample from a column fraction, for example, the presence of a higher than expected ratio of a certain amino acid is a very good indication that the sample is not pure and that further fractionation is indicated. In the same way, a lower than expected ratio could also indicate impurity—for example, the presence of a second protein that has a lower ratio of some significant amino acid present in higher amounts in the protein of interest. Because the expression of a protein in bacteria or other hosts utilizes a gene of known sequence, the expected amino acid composition is also known (see Chapters 5 and 6 for expression and purification of recombinant proteins).

Second, averaged composition yields an excellent measure of the amount of protein in a sample. On the ion-exchange-based Beckman 6300 amino acid analyzer running with ninhydrin detection chemistry, the minimum amount of the standard (a mixture of amino acids used to derive integration parameters as well as elution times) that is required is typically 1 nmol of each amino acid. Amounts as low as 250 pmol (0.25 nmol) of an amino acid can be measured with confidence from protein hydrolyzates. For a protein of 50 kDa mass, 1 nmol is 50 μg, an amount that can be obtained readily by purification of the protein from a high-expression system followed by purification by standard methods. For isolation of a trace protein from a natural source, this required amount may be too large to be feasible. However, a protein of 50 kDa mass contains ~400 amino acids, or roughly 20 copies of each amino acid on average. Thus, the actual amount of protein required for detection and semi-quantitative analysis could be as low as 0.05 nmol, or 2.5 μg. At that level, rare amino acids cannot be accurately quantitated, but the more common ones can be measured easily. Obviously, the more material available, the more accurate the analysis. Users should check with their local facility for specific advice on the amount of sample that can be processed by existing technologies.

The advent of advanced instrumentation, such as the Applied Biosystems 420 amino acid analyzer and the Waters PicoTag system, has provided another increment in sensitivity. These instruments utilize precolumn derivatization followed by separation based on reversed-phase high-performance liquid chromatography (HPLC). With such analyzers, 100 pmol of each amino acid, or 5 pmol of the 50-kDa protein described above, can be quantitated accurately.

Another important consideration in the design of a purification scheme that can be accomplished through the use of amino acid quantitation is the compilation of the mass balance—the relationship between how much protein is applied to the chromatography column and how much is recovered in a particular step. Amino acid analysis of a measured aliquot of the sample taken before application (typically ≤1%) along with aliquots of column frac-

BOWLING GREEN STATE UNIVERSITY LIBRARY

tions or pools, can be used to calculate the amounts of protein loaded and recovered. These calculations can provide essential information to assess the success of a particular purification procedure.

SAMPLE PREPARATION

The success or failure of quantitative amino acid analysis is strongly dependent upon the quality of the sample, as well as upon the exact composition of the sample matrix (i.e., the aggregate of all components including salts, detergent, and dirt). The following section gives a few key recommendations for successful sample preparation.

Sample Concentration

An ideal sample for amino acid analysis would contain 1 to 10 nmol protein in a volume of 10 to 100 µl water. A sample that has been dialyzed against a low concentration of buffer (if needed to maintain solubility) or pure water is optimal, because the presence of salt, detergent, high concentrations of buffers, or other agents may interfere with either hydrolysis or subsequent analysis.

A sample that has been lyophilized to dryness is also usually acceptable, with some important considerations. First, lyophilization should be done in such a way as to concentrate the lyophilized residue at the bottom of a conical tube. Drying a sample in a round-bottom flask may leave the protein sample spread over a large surface area. Such samples are extremely difficult to handle and will not give satisfactory results. Second, lyophilization of a buffered solution will concentrate the salts as well as the protein. Therefore, it is recommended that the total ionic strength of the solution be <50 µM before lyophilization.

Estimate of Total Protein

An estimate of the total amount of protein present is very helpful in planning an accurate analysis. This can be based on a colorimetric dye–binding assay, an A_{280} measurement, or an activity assay in which the results are compared to a standard value.

All information about the sample should be communicated to the individual charged with conducting the analysis to ensure the maximum return on the sample. Many facilities provide a form with a series of questions to be answered concerning the sample.

Samples from PVDF Blots

With the advent of more sensitive analyzers based on phenylthiohydantoin (PTH) chemistry, it is now possible to obtain compositional data on samples separated by electrophoresis and blotted onto membranes (*UNIT 10.7*) such as are used for protein sequence analysis. This is especially helpful in cases where a protein sample fails to yield any sequence during gas-phase Edman degradation. Acid hydrolysis and analysis of sample blot pieces recovered from the sequencer sample compartment yield a rough estimate of the amount of protein present. If the amount is larger than that normally required for sequence analysis (10 pmol), it may then be concluded that the protein sample was N-terminally blocked.

CALCULATION OF THE AVERAGE COMPOSITION

Table 3.2.1 presents the results of analysis of a 24-kDa recombinant protein. The initial sample volume was 1.0 ml and was expected to contain ~4 mg total protein. A 30-µl aliquot was taken for analysis and was estimated to contain 120 µg, or ~5 nmol. The aliquot was transferred to a glass tube for hydrolysis and dried by application of a vacuum at room temperature. One milliliter of 6 M HCl was added, the tube was cooled in a dry ice bath, then a vacuum was applied and the tube sealed by heating in a gas flame. Hydrolysis was conducted for 24 hr at 124°C, followed by removal of the HCl under vacuum. The sample was taken up in 1.0 ml application buffer, 50 nmol norleucine was added as an internal standard, and a 50-µl aliquot was analyzed by ion-exchange chromatography on a Beckman 6300 system with ninhydrin detection.

1. The total number of nanomoles of amino acids detected is first calculated by summing the second column of Table 3.2.1, yielding 1446 nmol.

2. The total nanomoles is then divided by the total number of expected amino acids (based on protein sequence; in this case, 212) to obtain the average number of nanomoles per residue; 1446 nanomoles/212 residues = 6.82 nmol per residue. If the total number of amino acids is not known, it may be estimated by dividing the mol. wt. of the protein by 110.

3. The number of nanomoles of each amino acid measured is divided by the average number of nanomoles per residue (step 2) to give the ratio[1] observed for that amino acid. For Asp, 155 ÷ 6.82 = 22.7.

The resulting ratios are given in the fourth column and may be compared to the ratio expected listed in the third column. For most

[a]Ratio expected based on amino acid sequence of protein.

of the amino acids, the ratio[1] observed agrees with the ratio expected.

The value of average nanomoles per residue calculated in step 2 is based on the analysis of a 30-µl sample; the total sample of 1 ml contains ~5.46 mg of protein (average moles/residue × grams/mole protein × 1000/30). This analysis utilized only 50 µl of the 1.0 ml final solution, so a sample size smaller than 3% of the original sample could have been used. Using an excess, however, provides the flexibility to repeat the determination if the first analysis gives peaks that are either too large or too small for accurate integration.

The ratio[1] observed for Ser, Thr, His, and Met are in this sample are ~30%, 13%, 24%, and 30% below the expected values, respectively. These results are typical for these four amino acids, but for different reasons. The Ser and Thr results are low because these amino acids undergo partial degradation during acid hydrolysis. Ser and Thr losses of 10% to 40% are normal. The lower-than-expected values for His and Met are an anomaly that is most likely caused by the relatively low copy number of those two amino acids in the protein. Due to these known problems, most investigators choose to delete the values for sensitive residues (Ser, Thr) as well as the values for those amino acids appearing in low amounts (in this case, His, and Met) and calculate the average number of nanomoles per residue independently of those amino acids. This gives the corrected ratios shown in the last column of Table 3.2.1 (ratio[2] observed). In this example, the recalculated values are changed by as much as 0.9 due to the higher average number of nanomoles per residue (7.11).

The deviation of ratio[1] observed from the expected ratio ranges from 1% to 32% for the various amino acids, with an average error of 8.8%. When the high variation for Ser (32%), Met (32%), and His (24%) are removed from consideration, the average deviation of ratio[2] observed from expected ratio drops to 4.1%. By standard criteria, this sample would be judged to be pure; of course, this result needs to be combined with electrophoretic separation (Chapter 10), chromatographic purification (Chapter 8), and perhaps mass spectroscopic analyses before a final assessment of the purity of the sample can be made.

In Vitro Radiolabeling of Peptides and Proteins

Radiolabeling of peptides or proteins is often performed to enhance the sensitivity of detection, to quantitate the binding of peptides to other molecules, or for radioimmunoassays. The choice of radioisotope depends in part on the amino acid residue(s) to be modified (Table 3.3.1). The most common and straightforward labeling strategy is radioiodination with ^{125}I because of its relative ease of use, the high resulting specific radioactivities (curies per millimole), and the convenience of detecting γ emissions. Radioiodination may also be performed with ^{131}I, which has a shorter half-life (8 days versus 60 days for ^{125}I), giving higher specific radioactivities but limiting the useful lifetimes of the labeled products; in addition, ^{131}I has higher-energy γ emissions, necessitating more shielding to protect workers.

Iodination at tyrosine or histidine residues using Iodo-Beads (Basic Protocol 1) is the most convenient method, but chloramine T or Iodogen (Alternate Protocol 1) may give higher recoveries when working with small quantities of peptide, and lactoperoxidase (Alternate Protocol 2) results in less oxidative damage and lower specific radioactivities, and is commonly used when labeling whole cells. Modifications for achieving equimolar or higher (stoichiometric) rather than trace iodination are presented in Support Protocol 1, and the optional separation of unlabeled peptide from iodinated products by HPLC is described in Support Protocol 2. For peptides that do not contain tyrosine or histidine, or in which labeling of these amino acid residues interferes with biological activity, ^{125}I or ^{131}I may be added onto primary amino groups (lysine residues and the peptide N-terminus) using Bolton-Hunter reagent (Basic Protocol 2).

As an alternative to iodination, peptides or proteins can be labeled with ^{14}C or ^{3}H by acetylation of primary amino groups using anhydride (Basic Protocol 3), by reductive alkylation of primary amino groups using aldehyde and borohydride (Alternate Protocol 3), or by alkylation of cysteine sulfhydryl groups (Alternate Protocol 4). Figure 3.3.1 summarizes these radiolabeling strategies as well as the basic iodination reactions. Two methods are available to label a peptide without altering its structure: ^{3}H labeling by catalytic reduction of (nonradioactive) ^{127}I-labeled peptide (Basic Protocol 4) and de novo peptide synthesis using a radiolabeled form of any amino acid (Basic Protocol 5). However, these methods tend to be more expensive and laborious. Finally, selective

labeling at the N-terminus of a peptide can be performed during peptide synthesis (Alternate Protocol 5).

All peptide-labeling procedures described in this unit are also applicable to larger proteins; however, with larger proteins there is increased potential for idiosyncratic results because of tertiary structure and for undesired side reactions because of sensitive amino acid residues (e.g., tryptophan, methionine, and cysteine in the case of oxidative iodinations). To some extent these problems may be minimized through the use of milder labeling procedures (e.g., lactoperoxidase-catalyzed iodination).

NOTE: Various methods for separating radiolabeling agents (e.g., free iodide) from labeled peptide products are described in Basic Protocol 1 and in *UNITS 8.2 & 8.3*, and any of these methods may be used in conjunction with any of the radiolabeling protocols in this unit. The choice of separation method should depend primarily on the properties of the peptide or protein (see Critical Parameters, discussion of iodination work-up).

CAUTION: When working with ^{125}I, ^{131}I, ^{14}C, ^{3}H, or other radiochemicals, always observe appropriate safety precautions, including the use of gloves (consider use of a glove box with a charcoal filter, particularly for >5 mCi iodide), shielding, dosimetry monitoring, and proper disposal of radioactive waste. Consult a radiation safety specialist to ensure that all procedures are safe and in accordance with Nuclear Regulatory Commission guidelines. Oxidation converts iodide to a volatile and hazardous form; peptide-bound iodine is not volatile, but emits γ radiation and remains a potential hazard. Be sure to perform all steps that may give rise to volatile iodine in an externally vented hood. See *APPENDIX 2B* for additional guidelines.

IODINATION AT TYROSINE OR HISTIDINE RESIDUES USING IODO-BEADS

BASIC PROTOCOL 1

Iodo-Beads are nonporous polystyrene beads with an immobilized oxidizing agent (*N*-chlorobenzenesulfonamide) capable of converting $Na^{125}I$ (or $Na^{131}I$) to its reactive form (Markwell, 1982). Iodination occurs by electrophilic addition to tyrosine at the two positions *ortho* to the hydroxyl group, and on histidine at two imidazole carbon positions (Means and Feeney, 1971; Fig. 3.3.1). After reaction of a peptide with oxidized iodide, the mixture is transferred to a solid-phase extraction device (e.g., a Sep-Pak cartridge) to remove free iodide from the labeled peptide.

Materials

Iodo-Beads (Pierce)
0.1 M sodium phosphate, pH 6.0 *or* pH 8.5
Carrier-free sodium iodide-125 ($Na^{125}I$; Amersham, Du Pont NEN, or ICN Biomedicals) or sodium iodide-131 ($Na^{131}I$)
0.1 M sodium hydroxide
Peptide, ideally dissolved in ≤0.4 ml of water or 0.1 M sodium phosphate
Methanol
HPLC solvent A: 0.1% (v/v) trifluoroacetic acid (TFA) in water
HPLC solvent B: 0.1% (v/v) TFA in acetonitrile

Filter paper
100-µl syringe with beveled tip, or hot pipettor (i.e., dedicated to radioactive use)
Luer-tipped syringes (1-, 5-, and 20-ml) and one 23-G needle
Solid-phase extraction device (e.g., Sep-Pak or Sep-Pak Plus C18 cartridge, Waters)
Polypropylene or other plastic tubes (12 × 75 mm)

BOSTON BIOMEDICAL RESEARCH INSTITUTE LIBRARY

1. Wash Iodo-Beads with 1 ml of 0.1 M sodium phosphate, pH 6.0 (for labeling primarily on tyrosine) or pH 8.5 (for labeling on histidine and tyrosine). Dry on filter paper and add to 0.5 ml of same buffer in capped microcentrifuge tube or small reaction vial.

   For trace labeling use two Iodo-Beads; for stoichiometric labeling more may be needed (see Support Protocol 1).

   Iodo-Beads are compatible with most salts (including azide), chaotropic agents, and detergents, but not with reducing agents or organic solvents that dissolve polystyrene such as dimethyl sulfoxide (DMSO) and dimethylformamide (DMF). Iodo-Beads must be stored in the presence of desiccant, and have a manufacturer-suggested shelf life of 1 year.

2. Add $Na^{125}I$ (or $Na^{131}I$) to Iodo-Beads in the reaction tube using a 100-µl syringe with beveled tip or a hot pipettor. Cap tube and wait 5 min at room temperature, agitating the mixture occasionally. Rinse syringe with 0.1 M sodium hydroxide (^{125}I is less volatile at high pH) and then with water before storing.

   The amount of radioactive iodide depends largely on the desired specific radioactivity, subject to safety and cost limitations; 1 to 5 mCi is typical. Use a fresh batch to minimize loss of radioisotope as volatile molecular iodine. $Na^{125}I$ is supplied in various concentrations of NaOH; the more dilute NaOH solutions are preferable since they are less likely to alter the pH of the reaction.

3. Add peptide to the reaction. Cap tube and wait 30 min, agitating occasionally.

   The amount of peptide is inversely related to the final specific radioactivity, unless iodinated products are separated from unlabeled peptide (see Support Protocol 2); 0.05 to 2.0 mg is typical. Reaction time can be 45 min or longer if desired, or just 5 to 10 min if oxidation-sensitive residues in the peptide (tryptophan, methionine, cysteine) are of concern, and should be optimized empirically if needed.

4. During the iodination reaction (or before if more convenient), prepare a Sep-Pak C18 cartridge by attaching a syringe and passing 5 ml methanol through the cartridge, followed by 5 ml water and 10 to 20 ml HPLC solvent A. Maintain a flow rate of ~2 ml/min, do not reverse the orientation of the cartridge when changing solvents, and avoid introducing air bubbles or allowing the cartridge to dry out.

   Although this Sep-Pak method offers the most efficient separation of unbound radioactive iodide from the peptide, anion-exchange (UNIT 8.2) or gel-filtration (UNIT 8.3) chromatography may be used as alternatives, especially for larger peptides at risk of denaturation under the conditions used in steps 4 to 8 (see Alternate Protocol 1, steps 1 and 4). Dialysis is another alternative for large peptides, but takes much longer.

5. Remove the mixture from the reaction tube using a 1-ml syringe fitted with a 23-G needle. Carefully remove the needle and slowly load mixture onto the preconditioned Sep-Pak cartridge, collecting the eluate into a radioactive liquid waste container.

6. Wash Sep-Pak cartridge with 20 ml HPLC solvent A, collecting the eluate as radioactive waste. Neutralize waste with 5 ml of 0.1 M sodium hydroxide.

   Unbound radioactive iodide will pass through the Sep-Pak cartridge under these conditions, while peptide will remain in the cartridge.

7. Elute two fractions from the Sep-Pak cartridge into 12 × 75–mm plastic tubes, the first using 4 ml of a 1:1 mixture of HPLC solvent A and HPLC solvent B, and the second using 4 ml HPLC solvent B.

   Usually the first tube contains most of the labeled peptide, but a two-step elution improves overall recovery. Because unbound iodide is now removed, the tubes may be transferred out of the glove box or other iodination facility, as long as appropriate shielding is maintained.

PGU IASRI CENTRAL UNIVERSITY LIBRARY

8. Dry the tubes in a Speedvac evaporator. Redissolve in water or desired buffer and pool the two fractions.

9. To determine the specific radioactivity of the labeled peptide, estimate peptide recovery or analyze an aliquot of the sample for peptide concentration (e.g., by a colorimetric assay) and simultaneously determine cpm (in a γ-radiation counter, possibly after serial dilutions in the presence of a carrier protein to reach a level of radioactivity within the linear counting range of the γ counter).

   Specific radioactivity (in cpm/μg) = measured radioactivity (in cpm/μl) ÷ peptide concentration (in μg/μl). To convert to millicuries, use 1 mCi = 2.22 × 10^9 dpm and cpm = dpm × counting efficiency of γ counter (often 50% to 75%, depending on the instrument).

   Alternatively, if iodinated products are separated from unlabeled peptide by HPLC and the molar ratio of incorporated iodide to peptide is known (or estimated), the specific radioactivity of the peptide may be calculated from that of carrier-free ^{125}I (or ^{131}I; see Support Protocol 2).

IODINATION AT TYROSINE OR HISTIDINE RESIDUES USING CHLORAMINE T OR IODOGEN

ALTERNATE PROTOCOL 1

Instead of using Iodo-Beads, $Na^{125}I$ can be oxidized to its reactive form using soluble chloramine T (*N*-chloro-4-methylbenzenesulfonamide sodium salt; Greenwood et al., 1963), the solid-phase reagent Iodogen (1,3,4,5-tetrachloro-3α,6α-diphenylglycoluril; Fraker and Speck, 1978), or the enzyme lactoperoxidase (see Alternate Protocol 2). Although slightly less convenient than Iodo-Beads, these methods may give higher recoveries when working with small quantities of peptide (<0.05 mg), which can adsorb to Iodo-Beads. The reagents are inexpensive and stable, and with Iodogen or lactoperoxidase, expose the peptide to relatively mild reaction conditions.

***Additional Materials** (also see Basic Protocol 1)*

Anion-exchange resin, e.g., Dowex 1-X8, chloride form, 100 to 200 mesh (Bio-Rad)
BSA solution: 1.0 mg/ml BSA in PBS, with 0.02% sodium azide (NaN_3)
1.0 mg/ml chloramine T in 0.1 M sodium phosphate, prepared immediately before use
Iodogen (Pierce), dichloromethane, and glass tubes or vials (optional alternate to chloramine T)
Saturated solution of tyrosine in water (~0.4 mg/ml at 25°C)
2.5 mg/ml sodium metabisulfite ($Na_2S_2O_5$) in 0.1 M sodium phosphate, prepared immediately before use (optional alternate to tyrosine solution)
Pasteur pipet or 1-ml syringe with glass wool plug inserted at bottom
Gel-filtration column, e.g., Sephadex G-10 or G-25 (Pharmacia Biotech), or Excellulose Desalting Column (Pierce; optional alternate to anion-exchange column)

1. Suspend Dowex resin in water and pour into plugged Pasteur pipet. Wash with ≥20 ml BSA solution. Alternatively, equilibrate a gel-filtration column with BSA solution. Avoid introducing air bubbles into the column and do not allow column to dry out.

   Because short peptides (<20 residues) are difficult to separate completely from unbound radioactive iodide by gel-filtration columns, an anion-exchange column may be preferred. Highly negatively charged (e.g., phosphorylated) peptides and very short peptides (<10 residues) may be retained on an anion-exchange column and should therefore be desalted by solid-phase extraction (see Basic Protocol 1). The desalting method should be established in advance.

BCU LASS CENTRAL UNIVERSITY LIBRARY

2a. *Chloramine T procedure:* Place peptide in a small tube and buffer with 0.1 M sodium phosphate, pH 6.0 or 8.5 (see Basic Protocol 1, step 1); bring the total volume to 100 to 300 µl. Add $Na^{125}I$ (or $Na^{131}I$), followed by 10 µl chloramine T (freshly prepared), and mix. Wait 1 min for reaction to occur.

2b. *Iodogen procedure:* Add sodium iodide to the peptide (as described in step 2a) in a glass tube previously coated with the solid-phase reagent Iodogen by dissolving the solid in dichloromethane and blowing off the solvent under a stream of dry nitrogen. Wait 10 min at room temperature.

Iodogen-coated tubes may be stored for many months at room temperature in a desiccator, protected from light. Because the oxiding agent is water insoluble, peptide damage is kept to a minimum.

3. Add 50 µl saturated tyrosine solution to quench the reaction.

Alternatively, the reaction may be terminated by adding 10 µl sodium metabisulfite, although this reducing agent is potentially more damaging to peptides.

4. Load mixture onto a Dowex or gel-filtration column and collect 0.5-ml fractions in 12 × 75–mm plastic tubes, using BSA solution for elution. Monitor fractions with a hand-held γ counter, or count 1-µl aliquots of each fraction in a γ counter to locate the peptide-containing fractions.

Radiolabeled peptide should pass through the column; unreacted iodide is retained longer and need not be eluted. Dispose of the entire column as radioactive sharps waste.

ALTERNATE PROTOCOL 2

IODINATION AT TYROSINE OR HISTIDINE RESIDUES USING LACTOPEROXIDASE

Although the degree of oxidative damage to peptides undergoing iodination is difficult to predict, the lactoperoxidase method results in less oxidative damage than chemical oxidative procedures (Marchalonis, 1969). Iodination is confined to tyrosine. Specific radioactivities are likely to be lower by this method. Because lactoperoxidase (mass 77,500 Da) will be iodinated during the reaction, it should be used only if the labeled peptide or protein of interest can be separated from labeled lactoperoxidase by gel filtration (*UNIT 8.3*), ion-exchange chromatography (*UNIT 8.2*), or some other means. Alternatively, it may be possible to use lactoperoxidase coupled to beads, or biotinylated lactoperoxidase and avidin-coated beads to remove the labeled enzyme (Sigma). Because the enzyme does not gain access to the cytoplasm, lactoperoxidase-catalyzed iodination is useful for selectively radiolabeling membrane proteins on whole cells, provided iodide concentrations are kept low and the proportion of dead cells is very small (Marchalonis et al., 1971).

Additional Materials (also see Basic Protocol 1)

0.2 mg/ml lactoperoxidase in PBS
0.01% hydrogen peroxide (H_2O_2) in PBS (diluted from 30% stock immediately before use)
2 U/ml glucose oxidase in PBS and 0.1 M D-glucose in PBS (optional alternate to H_2O_2)

1. Place peptide in a tube with PBS, ideally at ≥1.0 mg/ml in a small volume.
2. Add 10 µl of 0.2 mg/ml lactoperoxidase.

Azide should not be present in the reaction as it inhibits lactoperoxidase.

BCU IASL / CENTRAL UNIVERSITY LIBRARY

3. Add $Na^{125}I$ (or $Na^{131}I$), cap tube, and mix.

4. Add 10 µl of H_2O_2. Wait 10 min at room temperature.

   The H_2O_2 concentration is critical and may need fine-tuning for best results. Alternatively, use a coupled glucose/glucose oxidase system to generate H_2O_2 in situ, i.e., treat with 10 µl of glucose oxidase and 10 µl of glucose for 10 min at 4°C (Hubbard and Cohn, 1975).

5. Terminate the reaction and remove unbound radioactive iodide (see Alternate Protocol 1, steps 1, 3, and 4).

EQUIMOLAR IODINATION TO GIVE HIGH YIELDS OF PRODUCT

SUPPORT PROTOCOL 1

Iodination of microgram to milligram amounts of a peptide using low millicurie amounts of carrier-free $Na^{125}I$ (or $Na^{131}I$), such as those suggested in Basic Protocol 1 and Alternate Protocols 1 and 2, results in trace labeling (iodination of only a small fraction of the peptide molecules). For example, in a reaction between 1 mCi of ^{125}I (~600 pmol) and 500 µg of a peptide of mass 1000 Da (500 nmol) or a protein of mass 100,000 Da (5 nmol, or ~200 nmol of tyrosine residues on average), there is at most only enough ^{125}I to label well under 1% of the tyrosines. For proteins, trace labeling is often advantageous as it minimizes the chance that the protein's activity will be lost (Eisen and Keston, 1949; Hunter and Greenwood, 1962); moreover, a sizable fraction of protein molecules will have one iodine atom on at least one of its tyrosines. However, for short peptides over 99% of the molecules remain unmodified, greatly diluting the specific radioactivities that are possible and complicating the interpretation of experiments in which labeled and unlabeled peptides differ significantly in their activities (see Support Protocol 2).

To label a higher proportion of a peptide, nonradioactive $Na^{127}I$ ("carrier") can be added to ^{125}I, giving a higher yield of iodinated product and resulting in a mixture of chemically equivalent ^{125}I- and ^{127}I-labeled peptides. Perform all steps for iodination as described using Iodo-Beads (see Basic Protocol 1) or chloramine T or Iodogen (see Alternate Protocol 1), with two modifications. First, add 0.1 M $Na^{127}I$ in water to the $Na^{125}I$ prior to using $Na^{125}I$ in the indicated step. The amount of ^{127}I should be in moderate molar excess over the peptide (2- to 5-fold) to achieve high yields of iodinated products (70% to 95%). Further increasing the amount of ^{127}I unnecessarily diminishes the products' specific radioactivities: e.g., at a 4-fold molar excess of ^{127}I, only up to 25% of the ^{125}I added can be incorporated, at a 10-fold molar excess only 10% can be incorporated, etc. Second, a sufficient number of Iodo-Beads (or other oxidizing reagent) must be used to oxidize the total iodide (essentially ^{127}I). Use the manufacturer-determined oxidizing capacity of 0.55 ± 0.05 µmol per Iodo-Bead. Note that Iodo-Beads rapidly develop a yellow-brown color when stoichiometric amounts of iodide are added; failure to observe this color indicates deterioration of the beads.

For maximum specific radioactivities, label a small amount of peptide (e.g., 30 µg) with up to an equimolar amount of ^{125}I (e.g., 40 mCi) and separate the unlabeled peptide from iodinated products by HPLC (see Support Protocol 2).

It is also possible to iodinate with ^{127}I only, in which case the products will be nonradioactive but chemically equivalent to the corresponding radiolabeled products. This approach is useful for practicing the iodination procedure and for assessing the effects of iodination on a peptide's activity (Tsomides and Eisen, 1993), as well as for preparing an ^{127}I-labeled peptide to be reductively tritiated (see Basic Protocol 4).

BOSTON UNIVERSITY LIBRARY

SUPPORT PROTOCOL 2

SEPARATION OF UNLABELED PEPTIDE FROM IODINATED PRODUCTS BY HPLC

Whether trace iodinated with ^{125}I only or stoichiometrically iodinated with a mixture of ^{125}I and ^{127}I, some peptide will remain unlabeled, and it may be desirable to separate this unlabeled component from the iodinated products. To obtain chemically homogeneous radiolabeled peptides, iodinated products can be resolved from each other and from unlabeled peptide by reversed-phase HPLC. (This optional procedure is distinct from the obligatory separation of peptide from unbound radioactive iodide by solid-phase extraction, anion-exchange chromatography, gel filtration, exhaustive dialysis, or other means as detailed in steps 4 to 8 of Basic Protocol 1.) Because iodine is a bulky, hydrophobic atom relative to hydrogen, the retention times of iodinated peptides will be greater than those of their unlabeled counterparts on reversed-phase HPLC columns (e.g., C18 for short peptides, C4 for longer or more hydrophobic peptides).

In most iodinations, more than one product will be generated, even if the peptide has only a single tyrosine (see Fig. 3.3.1). Because the pK_a of monoiodotyrosine is lower than that of tyrosine (Edelhoch, 1962), electrophilic addition of the second iodine atom may be accelerated relative to the first; however, this reaction will not go to completion even when iodide is present in molar excess over the peptide. When more than two or three iodinatable residues (tyrosine and histidine) are present (as in a protein), the labeled products may be too complex to allow for individual resolution by HPLC, but unlabeled peptide can still be removed from the radiolabeled mixture. Even peptides as long as 50 to 100 residues can be separated from their iodinated derivatives by reversed-phase HPLC.

For peptides with a single iodinatable residue, the two products are usually easily separated by HPLC and can readily be identified by their specific radioactivities, which are in the ratio 1:2 for monoiodinated and diiodinated peptide, respectively. Figure 3.3.2 shows the result of stoichiometrically labeling 2.0 mg of an eight-residue peptide with 20

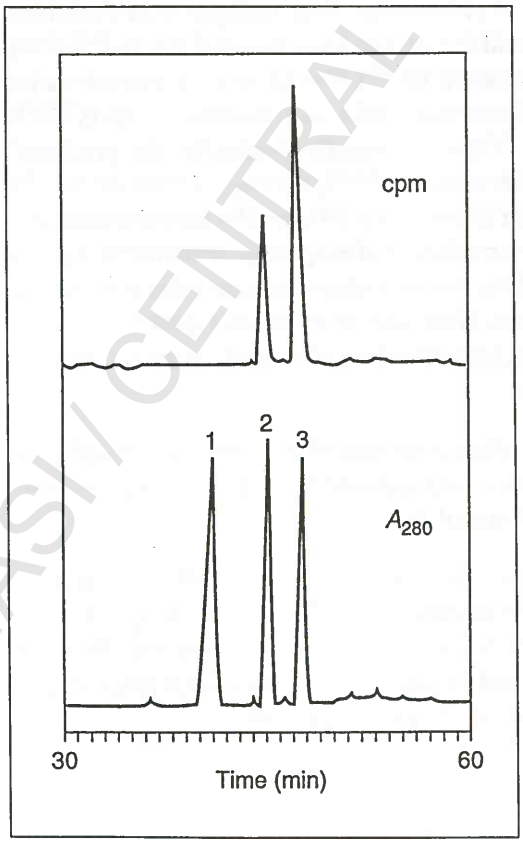

Figure 3.3.2 Stoichiometric iodination of the eight-residue peptide LSPFPYDL and HPLC separation of the unlabeled starting material (peak 1) from monoiodinated (peak 2) and diiodinated (peak 3) products. Two milligrams of peptide were iodinated with 20 mCi $Na^{125}I$ and 5 µmol $Na^{127}I$ at pH 7.0 using six Iodo-Beads, injected on a Vydac C4 semipreparative column, and eluted with an acetonitrile gradient of 1%/min at a flow rate of 3 ml/min. The specific radioactivities of the three peaks were $<10^5$ cpm/µg, 2.1×10^7 cpm/µg, and 4.6×10^7 cpm/µg, respectively.

PGU IASI / CENTRAL UNIVERSITY LIBRARY

mCi $Na^{125}I$ mixed with 5 μmol $Na^{127}I$ and separating the unreacted, monoiodinated, and diiodinated products by HPLC. If Edman degradation is available, labeled products may be characterized directly by detecting the monoiodinated and diiodinated derivatives of tyrosine and/or histidine (Tsomides and Eisen, 1993). Note that peptides containing tryptophan, methionine, or cysteine residues may undergo oxidation during iodination. The resulting oxidized products (both radiolabeled and unlabeled) may appear as separate peaks on HPLC, complicating the identification of products.

B.C.U. „M. Eminescu" IAŞI
CHIMIE

When carrying out stoichiometric iodination with a mixture of ^{125}I and ^{127}I, specific radioactivities of the product mixture or of individual HPLC-purified products can be measured as described for the Iodo-Beads procedure (see Basic Protocol 1, step 9). However, when trace labeling with ^{125}I only and removing unlabeled peptide by HPLC, specific radioactivities may simply be calculated as the specific radioactivity of carrier-free ^{125}I (~2000 Ci/mmol) multiplied by the molar ratio of ^{125}I to peptide (e.g., 1 for a monoiodinated derivative, 2 for a diiodinated derivative, etc.). When a mixture of ^{125}I-labeled products is separated from unlabeled peptide by HPLC but not resolved into its individual components, the same calculation may be applied by taking the average molar ratio of ^{125}I to peptide to be the number of iodinatable residues. For example, the specific radioactivity of a peptide of mass 1000 Da with two tyrosine residues that is labeled with ^{125}I and separated from unlabeled peptide by HPLC is $\sim 5 \times 10^9$ cpm/μg, assuming an average of two ^{125}I per labeled peptide.

NOTE: Although HPLC fractions can be analyzed for radioactivity by transferring them to a γ counter, it is preferable to use an on-line radioisotope detector connected in series with an ultraviolet absorbance detector (see Fig. 3.3.2).

IODINATION AT LYSINE RESIDUES OR N-TERMINUS USING BOLTON-HUNTER REAGENT

BASIC PROTOCOL 2

Many peptides do not contain tyrosine or histidine. Other peptides' function may be altered if crucial tyrosine or histidine residues are iodinated or if damage to oxidative-sensitive residues occurs during iodination. An alternate strategy is to label primary amino groups on lysine residues and/or at the N-terminus of the peptide using Bolton-Hunter reagent 3-(4-hydroxyphenyl)propionic acid *N*-hydroxysuccinimide ester (Bolton and Hunter, 1973). This reagent introduces a side chain similar to that of tyrosine (see Fig. 3.3.1). Of course, this method carries the potential drawback of altering peptide function if lysine residues (or the N-terminus) are critical for activity; unlike the methods above, peptide charge will be decreased by one unit for each site modified (at pH values below the amino group's pK_a value).

Because lysine's ε-amino group and the N-terminal α-amino group have different pK_a values (~10 vs. 8 to 9), it is possible, in principle, to achieve selective labeling by adjusting the pH (lower pH should favor the N-terminus). However, this is difficult in practice, and a mixture of products is to be expected from lysine-containing peptides unless the N-terminal residue is proline (secondary amine) or a protecting group is present on either lysine or the N-terminus.

^{125}I-labeled Bolton-Hunter reagent is commercially available in monoiodinated (~2000 Ci/mmol) or diiodinated (~4000 Ci/mmol) form. A cost-saving modification is to prepare ^{125}I-labeled Bolton-Hunter reagent from the less expensive unlabeled reagent by iodination using Iodo-Beads (see Basic Protocol 1) or chloramine T (see Alternate Protocol 1) followed by extraction of the product into anhydrous benzene. (In this case it is crucial to work quickly to minimize hydrolysis, and specific radioactivities will be lower unless unreacted Bolton-Hunter reagent is removed from the labeled product.) Alternatively, the

BCU IASI CENTRAL UNIVERSITY LIBRARY

peptide can first be modified with unlabeled Bolton-Hunter reagent and then radioiodinated using any of the methods previously described. Because ^{125}I-labeled Bolton-Hunter reagent suffers some degradation by competing hydrolysis during its reaction with peptide, this alternate approach gives a higher incorporation of radioactivity; however, it also results in the radiolabeling of any tyrosine or histidine residues present in the peptide, as well as exposure of the peptide to oxidative conditions.

Materials

0.1 M sodium borate, pH 8.5
0.1% (w/v) gelatin in 0.1 M sodium borate, pH 8.5
^{125}I-labeled Bolton-Hunter reagent (Amersham, Du Pont NEN, or ICN Biomedicals); or substitute unlabeled Bolton-Hunter reagent and iodinate later
Peptide, ideally ≥1 mg/ml in ≤100 µl of 0.1 M sodium borate, pH 8.5
1 M glycine in 0.1 M sodium borate, pH 8.5

Gel-filtration column, e.g., Sephadex G-10
Dry nitrogen tank and outlet tubing fitted with needle
Polypropylene or other plastic tubes (12 × 75 mm)

1. Equilibrate a gel filtration column with 0.1% gelatin/0.1 M sodium borate, pH 8.5, to prevent loss of radiolabeled peptide by nonspecific adsorption.

   BSA is not recommended as a carrier protein in place of gelatin because albumin binds to Bolton-Hunter reagent. If gelatin is undesired in the final preparation (e.g., iodination is to be performed later), condition the column and then reequilibrate in buffer of choice. Alternatively, use a Sep-Pak cartridge instead of gel filtration to separate by-products and salts from the labeled peptide (see Basic Protocol 1, steps 4 to 8).

2. Immediately prior to use, evaporate ^{125}I-labeled Bolton-Hunter reagent to dryness by inserting a needle through the rubber septum and admitting a gentle stream of dry nitrogen, using the manufacturer-supplied charcoal trap as a vent to contain any released volatile radioiodine. Do not splash solution onto upper parts of the vial.

   If using unlabeled Bolton-Hunter reagent, prepare a stock solution in anhydrous organic solvent and dilute into borate buffer at the time of reaction to achieve a 3- to 5-fold molar excess over peptide. Unlabeled Bolton-Hunter reagent is also available as a water-soluble (sulfo) derivative (at higher cost), obviating the need for organic solvent and offering an advantage for labeling cell surface proteins because the sulfo derivative is membrane impermeable.

3. Chill peptide in borate buffer to 0°C on ice. Add peptide to vial containing dried ^{125}I-labeled Bolton-Hunter reagent (or freshly dissolved unlabeled Bolton-Hunter reagent) and wait 15 to 30 min at 0°C, agitating the reaction occasionally.

   Incorporation is greatest when using high peptide concentrations. Phosphate or bicarbonate buffers, pH 8.5, may be used instead of borate, but avoid amine-containing buffers (ammonium, glycine, Tris) as well as azides and thiols. Being an N-hydroxysuccinimide ester, Bolton-Hunter reagent is sensitive to hydrolysis, with a half-life of a few hours at pH 7.0 and only ~10 min at pH 8.5; however, its reaction with amino groups is greatly accelerated at the higher pH since more amine is in the deprotonated (active) form.

4. Add 100 µl of 1 M glycine in 0.1 M sodium borate, pH 8.5, to quench the reaction and wait 5 min, or use a corresponding amount of Tris or any other amine for quenching.

   Longer incubations at 0°C (>4 hr) may improve yields and obviate the need for quenching by consuming all of the reagent.

PGU IASI LIBRARY

5. Load mixture onto gel filtration column and collect 0.5-ml fractions in 12 × 75–mm plastic tubes, using borate (or other) buffer for elution. Monitor fractions with a hand-held γ counter, or count aliquots of each fraction in a γ counter to locate the peptide-containing fractions.
6. Resolve products by HPLC if desired and determine specific radioactivities (see Support Protocol 2).

^{14}C OR ^{3}H LABELING AT LYSINE RESIDUES OR N-TERMINUS BY ACETYLATION USING ANHYDRIDE

BASIC PROTOCOL 3

There are two main advantages of labeling with ^{14}C or ^{3}H instead of ^{125}I. First, for peptides that are unacceptably altered as a result of iodination, different sites may be targeted for modification (i.e., lysine or cysteine), or the peptide may even be labeled without changing its structure by replacing carbon or hydrogen atoms with the corresponding radioisotope (see Basic Protocol 4 and Basic Protocol 5). Second, the half-lives of ^{14}C and ^{3}H are much longer than that of ^{125}I (5760 and 12.26 years, respectively, vs. 60 days), so labeling need not be done often. However, the specific radioactivities of peptides labeled with ^{14}C or ^{3}H are generally correspondingly lower, and the labeling techniques are not as widely applied as radioiodination. Also, counting β emissions involves the use of a liquid scintillation cocktail and is therefore slightly more cumbersome than counting γ emissions.

Acetylation with [^{14}C]- or [^{3}H]anhydride is a simple reaction that will modify amino groups (lysine and/or the N-terminus of a peptide; Fig. 3.3.1; Fraenkel-Conrat and Colloms, 1967). The most common side reaction is O-acetylation of tyrosine, which is reversible under mild alkali conditions (Means and Feeney, 1971).

CAUTION: All procedures should be carried out in an externally vented hood.

Materials

Saturated sodium acetate solution
Peptide, ideally ≥1 mg/ml in ≤100 µl H_2O or sodium acetate
[^{14}C]- or [^{3}H]acetic anhydride (Amersham, Du Pont NEN, ICN Biomedicals, or Sigma)
Acetic anhydride, unlabeled (optional)

1. Add 1 vol of saturated sodium acetate solution to the peptide (unless already in this buffer) and cool to 0°C on ice.
2. Add [^{14}C]- or [^{3}H]acetic anhydride, with or without 2 molar equivalents of additional unlabeled acetic anhydride, in four equal installments at 10- to 15-min intervals.

   Because the anhydride is rapidly hydrolyzed, addition over several installments is the preferred method. The use of excess unlabeled anhydride increases the extent of reaction but dilutes the specific radioactivity of the products (analogous to stoichiometric vs. trace iodination; see Support Protocol 1).

3. Remove by-products by gel filtration (*UNIT 8.3*), dialysis (*APPENDIX 3B*), or solid-phase extraction (see Basic Protocol 1, steps 4 to 8), and count fractions in an appropriate liquid scintillation cocktail.

   Resolution of individual products may be possible by HPLC (see Support Protocol 2).

BCU ASTON CENTRAL UNIVERSITY LIBRARY

ALTERNATE PROTOCOL 3

^{14}C OR ^{3}H LABELING AT LYSINE RESIDUES OR N-TERMINUS BY REDUCTIVE ALKYLATION

An alternative two-step procedure used to label peptides is treatment with an aldehyde followed by reduction of the resulting Schiff base with sodium cyanoborohydride (Fig. 3.3.1; Tack and Wilder, 1981; Jentoft and Dearborn, 1983). Most aldehydes give the monosubstituted alkylamine product, but formaldehyde goes on to give the dimethyl product. ^{14}C can be incorporated via the aldehyde, or ^{3}H can be added via labeled sodium cyanoborohydride. The latter gives higher specific radioactivities, reportedly ≥50 Ci/mmol. One advantage of this approach over acetylation is that the net charge on amino groups is not substantially altered (there is only a small change in pK_a value).

CAUTION: All procedures should be carried out in an externally vented hood.

Materials

0.2 M sodium borate, pH 9.0
Peptide, ideally ≥1 mg/ml in 0.1 to 1.0 ml of 0.2 M sodium borate, pH 9.0
[^{3}H]sodium borohydride (Amersham, Du Pont NEN, or ICN Biomedicals) or [^{3}H]sodium cyanoborohydride (Amersham)
0.01 M NaOH
37% (12.4 M) formaldehyde stock
[^{14}C]formaldehyde and unlabeled sodium cyanoborohydride (optional alternative for labeling with ^{14}C instead of ^{3}H)

1. Add an equal volume of 0.2 M sodium borate, pH 9.0, to the peptide (unless already in this buffer) and cool to 0°C on ice.

2. Dilute formaldehyde stock (12.4 M) to 0.1 to 0.2 M and add to peptide on ice to give a 2- to 6-fold molar excess over amino groups (e.g., 10 to 20 µl).

   More concentrated formaldehyde in this step may lead to peptide cross-linking.

   For ^{14}C labeling, use [^{14}C]formaldehyde in this step.

3. Immediately dissolve [^{3}H]sodium borohydride (or [^{3}H]sodium cyanoborohydride) in 0.01 M NaOH to a final concentration of 1.0 Ci/ml and add to peptide on ice for 10 min. Use a molar ratio of sodium borohydride to formaldehyde of between 0.25 and 0.40 (e.g., 30 to 50 µl).

   Sodium cyanoborohydride is a superior reagent for this purpose because it reduces the Schiff base formed initially between the peptide and formaldehyde without reducing disulfides or aldehydes. [^{3}H]sodium borohydride or [^{3}H]sodium cyanoborohydride should be stored frozen in small aliquots rather than frozen and thawed repeatedly.

   For ^{14}C labeling, use unlabeled sodium cyanoborohydride in this step.

4. Remove by-products by gel filtration (*UNIT 8.3*), dialysis (*APPENDIX 3B*), or solid-phase extraction (see Basic Protocol 1, steps 4 to 8), and count fractions in an appropriate liquid scintillation cocktail.

   Resolution of individual products may be possible by HPLC (see Support Protocol 2).

UCLA IASL - CHARLES E. YOUNG RESEARCH LIBRARY

^{14}C OR ^{3}H LABELING AT CYSTEINE RESIDUES USING IODOACETIC ACID OR IODOACETAMIDE

ALTERNATE PROTOCOL 4

To label cysteine residues, a peptide is reduced and allowed to react with either iodoacetic acid (to give the carboxymethyl derivative) or iodoacetamide (to give the carboxamidomethyl derivative, which is uncharged; see Fig. 3.3.1). For large peptides containing disulfide bonds, this procedure is often used to denature the peptide irreversibly. Carboxymethylcysteine content is readily determined by amino acid analysis following acid hydrolysis. [^{14}C]- or [^{3}H]iodoacetic acid and [^{14}C]iodoacetamide are commercially available for radiolabeling. Possible side reactions are alkylation of histidine, methionine, or lysine, each of which can usually be controlled by pH and other reaction conditions (Crestfield et al., 1963; Means and Feeney, 1971).

CAUTION: All procedures should be carried out in an externally vented hood.

Materials

0.5 M Tris·Cl/6 M guanidine·HCl/0.002 M disodium EDTA, pH 8.6
Peptide, ideally ≥1 mg/ml in 0.1 to 1.0 ml 0.5 M Tris·Cl/6 M guanidine·HCl/0.002 M disodium EDTA, pH 8.6
Dithiothreitol
1.0 M NaOH
[^{14}C]- or [^{3}H]iodoacetic acid or [^{14}C]iodoacetamide (Amersham, Du Pont NEN, or ICN Biomedicals)
Iodoacetic acid or iodoacetamide, unlabeled (optional)

1. Peptides containing disulfide bonds or significant tertiary structure require reduction and/or denaturation prior to alkylation of cysteine residues. For this, prepare a solution of peptide in 0.5 M Tris·Cl/6 M guanidine·HCl/0.002 M disodium EDTA (pH 8.6), incubate for 1 hr at 37°C, add dithiothreitol (50-fold molar excess over disulfide), and incubate overnight at 37°C.

2. Cool to room temperature and add desired amount of radiolabeled iodoacetic acid (or iodoacetamide) dissolved in 1/10 vol of 1.0 M NaOH for 30 min in the dark.

   Optionally, include additional unlabeled iodoacetic acid (or iodoacetamide) at a 2-fold molar excess over the dithiothreitol added to increase the extent of the reaction (analogous to stoichiometric vs. trace iodination; see Support Protocol 1).

3. Remove by-products by gel filtration (*UNIT 8.3*), dialysis (*APPENDIX 3B*), or solid-phase extraction (see Basic Protocol 1, steps 4 to 8), and count fractions in an appropriate liquid scintillation cocktail.

   Resolution of individual products may be possible by HPLC (see Support Protocol 2).

^{3}H LABELING AT TYROSINE RESIDUES BY REDUCTION OF ^{127}I-LABELED PEPTIDE

BASIC PROTOCOL 4

It is possible to label one or more tyrosine residues of a peptide stoichiometrically with ^{3}H to a relatively high specific radioactivity (e.g., 50 Ci/mmol). Since ^{3}H substitutes for hydrogen, the peptide's structure remains unaltered. However, this approach is more laborious and expensive than the previous methods, requiring the preparation of a ^{127}I-labeled peptide that is then catalytically reduced in the presence of tritium gas, leading to replacement of each ^{127}I (or other halogen atom) with ^{3}H.

The ^{127}I-labeled peptide precursor can be produced in two ways: by stoichiometric iodination with ^{127}I (see Basic Protocol 1, Support Protocol 1, and Support Protocol 2) or by incorporating a suitably protected ^{127}I-labeled tyrosine derivative (either mono-

BOULDER CENTER UNIVERSITY LIBRARY

iodinated or diiodinated) during de novo peptide synthesis (e.g., *N*-Boc-O-3-bromobenzyl-3,5-diiodo-L-tyrosine, available from Peninsula). The ^{127}I-labeled peptide is then submitted to a specialized facility for reductive tritiation (Amersham and Du Pont NEN offer this service).

BASIC PROTOCOL 5

INTRODUCTION OF LABELED AMINO ACID RESIDUES DURING PEPTIDE SYNTHESIS

The most specific and least disruptive labeling procedure is incorporation of a suitably protected radioactive amino acid into any desired position of a peptide during its solid-phase synthesis. However, because this requires an entire synthesis rather than use of just an aliquot of peptide, and because the protected derivatives of radioactive amino acids are not generally available and therefore must be prepared, it is not commonly done. Furthermore, introduction of a radioactive amino acid into a peptide synthesizer will be possible only if the operator of the instrument is prepared to work with radioactive samples. However, amino acids containing ^{14}C, ^{3}H, or ^{35}S (for methionine) are available, procedures for attaching various protecting groups to these amino acids are quite well established, and the result may be an abundant supply of a radiolabeled peptide unperturbed in structure and not obtainable by any other means. Specific radioactivities are typically two to three orders of magnitude lower than for radioiodinated peptides.

The simplest approach is to select a radioactive amino acid that requires protection during solid-phase peptide synthesis only on its α-amino group and not on its side chain (e.g., ^{14}C- or ^{3}H-labeled alanine, isoleucine, leucine, valine, or phenylalanine, all available from Amersham, Du Pont NEN, ICN Biomedicals, or Sigma). If classical *t*-butyloxycarbonyl (*t*-BOC) chemistry is to be used during peptide synthesis, a variety of procedures are available for attaching *t*-BOC to α-amino groups (Stewart and Young, 1984); one such procedure is outlined below for leucine.

Materials

L-Leucine, unlabeled
L-[^{14}C]- or L-[^{3}H]leucine, 1 to 5 mCi
Triethylamine
2-(*t*-butoxycarbonyloxyimino)-2-phenylacetonitrile (BOC-ON, Aldrich)
Dioxane
Diethyl ether, anhydrous
1.0 M HCl, 4°C
Separatory funnel

1. Add 131 mg L-leucine (1 mmol) and the desired number of millicuries L-[^{14}C]- or L-[^{3}H]leucine (supplied in water) to a 25-ml round-bottom flask.

   Other amino acids or their side chain protected derivatives can be substituted for leucine. Unlabeled amino acid is used because the amount of ^{14}C- or ^{3}H-labeled material is very small in molar terms (e.g., 2 mCi [^{3}H]leucine is <1 μmol); safety and cost considerations generally preclude the use of stoichiometric amounts of radiolabeled amino acid.

2. Add 210 μl triethylamine (1.5 mmol).

3. Add 271 mg BOC-ON (1.1 mmol).

4. Add a mixture of 600 μl dioxane and enough water to bring the total volume of water to 600 μl; e.g., if the radiolabeled amino acid is supplied in 400 μl water, add 600 μl dioxane and 200 μl water.

FGCU IASL / CENTRAL UNIVERSITY LIBRARY

5. Stir with a magnetic stir bar 3 hr at room temperature. The yellow, heterogeneous reaction will become homogeneous.

6. Add 2 ml water and 2 ml diethyl ether and transfer the reaction mixture to a separatory funnel.

   The aqueous (bottom) layer contains the triethylammonium salt of the t-BOC-amino acid product; the ether (upper) layer contains an oxime by-product from the reaction (bright yellow).

7. Drain the aqueous layer and wash it three times with an equal volume of diethyl ether in the separatory funnel to remove unwanted oxime.

8. Add a small volume of 4°C 1.0 M HCl to bring the aqueous layer to pH 2 and precipitate the *t*-BOC-amino acid product.

9. Add an equal volume of diethyl ether to the aqueous layer in the separatory funnel, shake, and drain off the aqueous layer. Save the ether layer and repeat ether extraction of the aqueous layer two more times. Pool the combined ether layers into an Erlenmeyer flask.

   The t-BOC-amino acid product now partitions into the ether layer after being converted by HCl from a salt to the free acid. Some t-BOC-amino acids (serine, threonine) remain soluble in water and are best extracted if the aqueous layer is first saturated with NaCl before adding ether.

10. Allow the product to crystallize for several hours on ice or overnight at 4°C. First blowing off some ether with a gentle stream of dry nitrogen gas may be helpful. Wash the white, crystalline product carefully with cold diethyl ether.

    The t-BOC-amino acid should be checked for nonreactivity of its amino group by a ninhydrin (Sarin et al., 1981) or other analytical test prior to using it in peptide synthesis.

SELECTIVE LABELING ON N-TERMINUS DURING PEPTIDE SYNTHESIS

ALTERNATE PROTOCOL 5

The N-terminus of a peptide that contains one or more lysine amino groups can be selectively labeled after the peptide has been synthesized by solid-phase methods but before amino acid side chains (including that of lysine) have been deprotected. For example, N-terminal acetylation of a newly synthesized protected peptide can be used to label the peptide with ^{14}C or ^{3}H without affecting lysine residues that might be important for activity (see Basic Protocol 3). Alternatively, addition of a Bolton-Hunter group allows subsequent iodination at this position (see Basic Protocol 2); tyrosine, if present, will also be iodinated unless radiolabeled Bolton-Hunter reagent is used.

Various other reagents can be used to modify a peptide at its N-terminus. For example, a dinitrophenyl (DNP) group can be attached specifically to the N-terminus of a protected resin-bound peptide using dinitrofluorobenzene (100 mol equivalents), *N,N*-diisopropylethylamine (20 mol equivalents), and dichloromethane as the solvent for the coupling reaction (2 hr at room temperature with shaking in the dark; T. Tsomides, unpub. observ.).

Specific details of the protocols to be used for N-terminal labeling reactions depend on the particular chemistries involved in the peptide's synthesis and cleavage. In particular, any label attached selectively to the N-terminus must be stable during the peptide side chain deprotection step (e.g., hydrogen fluoride or trifluoroacetic acid). In the example above, DNP is stable during deprotection with trifluoromethane sulfonic acid.

BRUNEL CENTRAL UNIVERSITY LIBRARY

COMMENTARY

Background Information

Detection of minute quantities of a peptide or protein is often made possible by radiolabeling procedures. The most common labeling strategy, radioiodination with ^{125}I, is relatively straightforward to perform and low in cost. Thus, a peptide with two tyrosine residues can be radiolabeled with ^{125}I to a specific radioactivity of 5×10^9 cpm/μg (see Support Protocol 2), allowing its detection at subfemtomole levels, or several orders of magnitude lower than absorbance- or fluorescence-based detection methods (*UNIT 3.1*).

The main drawback of radioiodination (other than the need to work safely with a potentially hazardous radioisotope) is that some peptides may be unreactive or may be damaged by the introduction of iodine atoms (each as large as a phenyl ring) or by the oxidative conditions typically employed during the labeling reaction. These problems may be more acute for a large protein with native tertiary structure and more oxidation-sensitive residues (tryptophan, methionine, and cysteine) than for a short peptide; nevertheless, even small peptides can be significantly altered in their biological activities by iodination. In most cases these problems can be obviated by modifying the radiolabeling strategy (see Table 3.3.1).

Standard radioiodination methods rely on the oxidation of ^{125}I (in the form of $Na^{125}I$) to its reactive state (which can be considered "I^+") for electrophilic addition to the phenolic and imidazole side chains of the amino acids tyrosine and histidine, respectively (see Fig. 3.3.1). At a pH between 6 and 7, tyrosine labeling predominates, whereas at a higher pH there is also labeling on histidine (Wolff and Covelli, 1969; Tsomides and Eisen, 1993). Different methods of oxidizing the ^{125}I include Iodo-Beads (a convenient immobilized form of chloramine T; Basic Protocol 1), soluble chloramine T, and Iodogen (a water-insoluble reagent plated onto tubes prior to use; Alternate Protocol 1). A gentler oxidative procedure uses the enzyme lactoperoxidase along with hydrogen peroxide (Alternate Protocol 2). All four methods can be expected to give reasonable specific radioactivities (lowest for lactoperoxidase), and their relative merits have been assessed for some peptides (Thean, 1990; Rizzino and Kazakoff, 1991).

For peptides that lack tyrosine and histidine or that are unacceptably altered by standard iodination procedures, an alternate strategy is to label free amino groups (lysine side chains and the peptide N-terminus, unless it is proline or blocked) using an iodinated acylating agent (e.g., Bolton-Hunter reagent; see Basic Protocol 2 and Fig. 3.3.1; Bolton and Hunter, 1973). This mild coupling reaction avoids direct contact of the peptide or protein with harsh oxidizing conditions, but the resulting labeled product is likely to have a lower specific radioactivity (because Bolton-Hunter reagent suffers competing hydrolysis during the reaction); a second drawback is the relatively high cost of this reagent. A similar though less commonly tried modification using an iodinated amidinating reagent (Wood et al., 1975) has the potential advantage that the positive charge on lysine (pK_a~10) is retained in the final labeled product (an amidine with pK_a 11.5 to 12.5).

Besides labeling with ^{125}I, it is straightforward to radiolabel peptides or proteins with ^{14}C or ^3H using various methods (see Table 3.3.1). This may be desirable if all iodination options fail, or if it is critical to obtain a radioactive product devoid of structural alterations. Usually the products of ^{14}C or ^3H labeling will have much lower specific radioactivities than the products of ^{125}I labeling, reflecting the different disintegration rates for these radioisotopes (~35,000 and 75 times lower for ^{14}C and ^3H, respectively, than for ^{125}I). Also, counting β emissions requires liquid scintillants and is therefore less convenient than counting γ emissions, which requires no additives to the sample. However, the longer half-lives of ^{14}C and ^3H (5760 and 12.26 years, respectively) render the resulting products useful for much longer than ^{125}I-labeled products ($t_{1/2}$ ~60 days).

A selection of protocols for labeling a peptide with ^{14}C or ^3H is given in this unit: acetylation on amino groups with acetic anhydride (see Basic Protocol 3), reductive alkylation on amino groups with formaldehyde and sodium cyanoborohydride (see Alternate Protocol 3), and alkylation on cysteine with iodoacetic acid or iodoacetamide (see Alternate Protocol 4). Each of these procedures results in modification of the peptide structure, albeit on different residues than does standard radioiodination (Fig. 3.3.1). To label a peptide without altering its structure, two alternatives are available: ^3H labeling by catalytic reduction of (nonradioactive) ^{127}I-labeled tyrosine (see Basic Protocol 4), and de novo peptide synthesis using a radiolabeled (and suitably protected) amino acid

UCU IAS LIBRARY

derivative (see Basic Protocol 5; Stewart and Young, 1984). These methods are much more laborious and costly, but may be useful when modification of a peptide's structure is unacceptable.

Critical Parameters and Troubleshooting

Amount of radioisotope

The amount of radioisotope to be used is often a compromise among the desire for high specific radioactivities (curies per millimole or cpm per microgram), a practical limit to the amount of radioactivity that can be afforded and safely handled, and (particularly for a large protein) any risk of altering tertiary structure by excessive substitution or radiation damage. Commonly, 1 to 5 mCi of ^{125}I (or ^{131}I) is used; however, it is possible to scale up the ^{125}I and increase specific radioactivities proportionately, because iodide is almost always limiting relative to iodinatable sites (e.g., 2 mCi ^{125}I is only ~1.2 nmol). Conversely, lowering the amount of peptide or protein will also improve specific radioactivities, but lowering the amount of substrate too far will cause unacceptable losses of material by nonspecific adsorption to tubes; a practical lower limit is 5 to 10 μg of peptide.

Sensitive amino acid residues

During oxidative iodinations, the amino acid residues at greatest risk for damage are tryptophan, methionine, and cysteine. The problem is greatest for tryptophan, as an oxidized indole ring cannot be restored by subsequent treatment with a reducing agent such as dithiothreitol. When these residues are critical for peptide function, the lactoperoxidase or Bolton-Hunter methods may be preferred for ^{125}I labeling.

Iodination work-up

Several options are available for the removal of unbound radioactive iodide from a peptide once the reaction is complete, including solid-phase extraction (e.g., using Sep-Pak cartridges; Basic Protocol 1), anion-exchange chromatography (*UNIT 8.2*), gel filtration (*UNIT 8.3*), and dialysis (*APPENDIX 3B*). The choice of desalting procedure will depend on the peptide, particularly its size and charge. For small peptides the Sep-Pak method works well, because the peptide binds to the Sep-Pak cartridge, allowing extensive washing to remove all traces of free iodide (Tsomides and Eisen, 1993). For larger peptides and proteins, anion-exchange chromatography (e.g., Dowex column) and gel filtration are popular, as the peptide is eluted immediately while iodide is retained on the column. To ensure that the removal of unbound iodide is complete, many investigators precipitate a radiolabeled protein with trichloroacetic acid (TCA) to determine the proportion of TCA-precipitable counts. Dialysis is a time-consuming but effective method for removing traces of iodide, provided the peptide is large enough to be retained by the dialysis membrane used.

Note that for highly negatively charged peptides, there may be some retention on anion-exchange columns. For peptides of 10 to 20 amino acids, separation of labeled peptide from free iodide may be poor on an anion-exchange or gel-filtration column because the peptide's molecular mass is so close to the exclusion limit of the column. For such peptides the Sep-Pak method may be advantageous.

Once unbound radioactive iodide has been removed, the labeled peptide mixture can be used as is, or the individual products can be separated from each other as well as from the unreacted peptide that is almost always present (see Support Protocol 2). If unlabeled peptide is removed by reversed-phase HPLC, the specific radioactivity of the labeled peptide will be maximized and will equal the specific radioactivity of carrier-free ^{125}I (~2000 Ci/mmol) multiplied by the number of ^{125}I atoms incorporated per peptide molecule.

Poor iodination results

Table 3.3.2 gives potential causes and possible remedies for poor iodination results.

Anticipated Results

In radioiodinating a purified protein, it is customary to aim for incorporation of up to one ^{125}I atom per protein molecule, i.e., ~20 μCi/μg for a protein of molecular mass 100,000 Da. For short peptides it is rare to label all the molecules, but specific radioactivities are typically on the same order (e.g., 20 μCi/μg for a peptide of mass 1000 Da, representing only 1% of the peptide labeled and 99% unlabeled). More labeled peptide is obtained when nonradioactive ^{127}I is added during the iodination reaction (see Support Protocol 1). For example, Figure 3.3.2 shows the results of iodinating an eight-residue peptide with 20 mCi ^{125}I and 5 μmol ^{127}I, followed by separating the products from unlabeled peptide by HPLC.

POLARY CENTRAL UNIVERSITY LIBRARY

Table 3.3.2 Troubleshooting the Iodination Reaction

Problem	Potential cause	Possible remedy
Poor iodine incorporation	Peptide contains reducing agent, e.g., from synthesis/cleavage	HPLC-purify or desalt peptide prior to use
	Peptide contains detergent or other component that becomes iodinated	HPLC-purify peptide
	Tyrosine/histidine residues are unreactive because of tertiary structure	Treat peptide with denaturing agent Use alternate strategy, e.g., Bolton-Hunter reagent
	Iodo-Beads are unreactive	Test for color (see Support Protocol 1); use fresh lot
Poor peptide recovery	Solubility problem	Change solvent system or adjust pH
	Failed elution from Sep-Pak	Replace with ion exchange, gel filtration, or dialysis
	Nonspecific losses	Increase amount of peptide or add carrier protein (after iodination reaction)
		Use chloramine T instead of Iodo-Beads
Labeled peptide unreactive	Tyrosine is crucial for activity	Iodinate for shorter time and/or use less label
		Use alternate strategy, e.g., Bolton-Hunter reagent
	Other peptide damage	Use alternate strategy

Time Considerations

Each of the listed protocols is easily completed within a few hours (not including HPLC purification if chosen), and with practice can be done in even less time. The resulting radioactive peptides will, of course, decay according to the half-life of the radioisotope used (or in some cases faster, if there is radiation damage). To calculate specific radioactivity after t days, simply multiply the initial specific radioactivity by $2^{(-t/t_{½})}$, where $t_{½}$ is the half-life of the radioisotope (60 days for ^{125}I).

Assays for Total Protein

Total protein assays are used to analyze hundreds of industrial, agricultural, and biotechnology products. They are also basic for research purposes, especially for determining the specific activity (i.e., total activity/total protein) of enzymes, antibodies, and lectins. Clearly, accuracy and precision of specific activity measurements depend as much on accurate measurement of total protein as on determination of total activity.

In performing total protein assays, there are five issues of concern: (1) sensitivity and technique of the method, (2) clear definition of units, (3) interfering compounds, (4) removal of interfering substances before assaying samples, and (5) correlation of information from various techniques. These concerns are discussed at length in the Commentary of this unit.

This unit describes three copper-based assays to quantitate total protein: the biuret method (Basic Protocol 1), a variation of the Lowry method (Hartree-Lowry method; Basic Protocol 2), and the bicinchinonic acid (BCA) assay (Basic Protocol 3). Acid hydrolysis of a protein is coupled with ninhydrin detection to quantitate amino acid content of a sample (Basic Protocol 4). Ultraviolet spectrophotometry is used to measure total protein (Basic Protocol 5) and evaluate samples for the presence of contaminants. The Coomassie dye binding, or Bradford, assay (Basic Protocol 6) is a quite simple assay and frequently is quite sensitive, although it sometimes gives a variable response depending on how well or how poorly the protein binds the dye in acid pH. Finally, dry weight measurement (Basic Protocol 7) is used to quantitate pure protein. Support protocols describe a technique for heat sealing glass tubes (Support Protocol 1) for acid hydrolysis, sample dialysis in polyacrylamide gel wells to remove low-molecular-weight contaminants (Support Protocol 2), and TCA precipitation to precipitate and concentrate proteins and remove low-molecular-weight contaminants (Support Protocol 3).

BIURET ASSAY FOR QUANTITATION OF TOTAL PROTEIN

BASIC PROTOCOL 1

Biuret assays are the oldest and least sensitive assays for total protein among the colorimetric (spectrophotometric) methods. Nevertheless, the biuret assay is still frequently used because it is easy to perform, reagents are easily prepared, and the assay is markedly less susceptible to chemical interference than other copper-based assays. The assay is based on polypeptide chelation of cupric ion (colored chelate) in strong alkali. Catalog listings for many commercially available proteins and enzymes include their specific activities based on biuret protein (mg-biuret-protein^{-1}). In general, biuret assays are useful for samples containing ~1 to 10 mg protein/ml, which is diluted ~5-fold by the added reagent to give a concentration of 0.2 to 2 mg/ml final assay volume (f.a.v.). Most proteins produce a deep purple color, with maximum absorbance (λ_{max}) at 550 nm.

Materials

Calibration standard: e.g., 10 to 20 mg/ml BSA (see Table 3.4.1)
Buffer or solvent used to prepare the protein-containing sample
Sample containing protein at 1 to 10 mg/ml
Biuret reagent (see recipe)
Spectrophotometer and 1-cm cuvettes

1. Prepare a dilution series of calibration standard in the buffer or solvent used to prepare the sample.

   Use bovine serum albumin (crystallized or lyophilized or one of the Cohn Fraction V preparations which are 96% to 98% protein and 3% to 4% water; Sigma) for the

BOSTON / CENTRAL UNIVERSITY LIBRARY

Table 3.4.1 Slopes of Calibration Plots for the Biuret Assay[a]

Protein	Assay conditions	Slope [A_{650} (μg/ml f.a.v.)$^{-1}$cm^{-1}]
BSA	—	2.3×10^{-4}
BSA	—	2.6×10^{-4}
BSA	Glucose concentration 0.4 to 400 mM	2.7×10^{-4}
BSA	—	2.7×10^{-4}
β-lactoglobulin	—	2.5×10^{-4}
Cellulase enzymes	—	2.2×10^{-4}
BSA[b]	—	3.2×10^{-4}
BSA[c]	—	1.9 to 2.8×10^{-4}
BSA[d]	—	2.3×10^{-4}

[a]Abbreviations: BSA, bovine serum albumin; f.a.v., final assay volume.
[b]Watters (1978).
[c]Goshev and Nedkov (1979).
[d]Beyer (1983).

calibration standard. Concentrations of albumin in the final assay volume (f.a.v.) of 5 ml may range from ~0.40 to 2.50 mg protein/ml—to produce A_{550} readings from ~0.10 to 0.70 in 1-cm. cuvettes—so the dilution series should run from 2 to 12.5 mg/ml.

2. In separate test tubes, add 1 ml of protein-containing sample, of each dilution of the calibration standard, or of the buffer or solvent used to prepare the sample (reference standard) to 4 ml biuret reagent. Incubate 20 min at room temperature.

   The modest amounts of detergent (e.g., deoxycholate or SDS) used to help solubilize proteins from tissue or insoluble biomaterials that will be added with the protein sample have negligible effects on this assay (see references in Table 3.4.1), although they sometimes have marked effects on the Hartree-Lowry assay (Basic Protocol 2). Mild reducing agents and strong oxidizers adversely affect the assay.

3. Measure the net absorbance of the sample, calibration standards, and reference standard at 550 nm (A_{550}) in 1-ml cuvettes. If the spectrophotometer does not automatically give net absorbance readings, subtract the value of the reference standard from those obtained for the sample and calibration standards.

   Sample should not be diluted after the addition of biuret reagent. In general, reaction mixtures for spectrophotometric assays should not be diluted after development even if the color (absorbance) is too intense. Dilution will decrease the required excess of cupric ion, thus upsetting chemical equilibria. If the sample has an A_{550} >1 or 2 (depending on the spectrophotometer), dilute a sample of the original protein and repeat the assay.

4. Prepare a calibration plot by graphing the net A_{550} values for the standards versus protein concentration (μg protein/ml f.a.v.). Determine the protein concentration of the sample by interpolation from the plot.

   Plot the data as shown in Figure 3.4.1 and calculate the slope and its units. (The plots in this unit show net absorbance as the ordinate.) The slope of this plot is directly proportional to the apparent spectrophotometric absorption coefficient (the sensitivity of the assay) in the same units.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

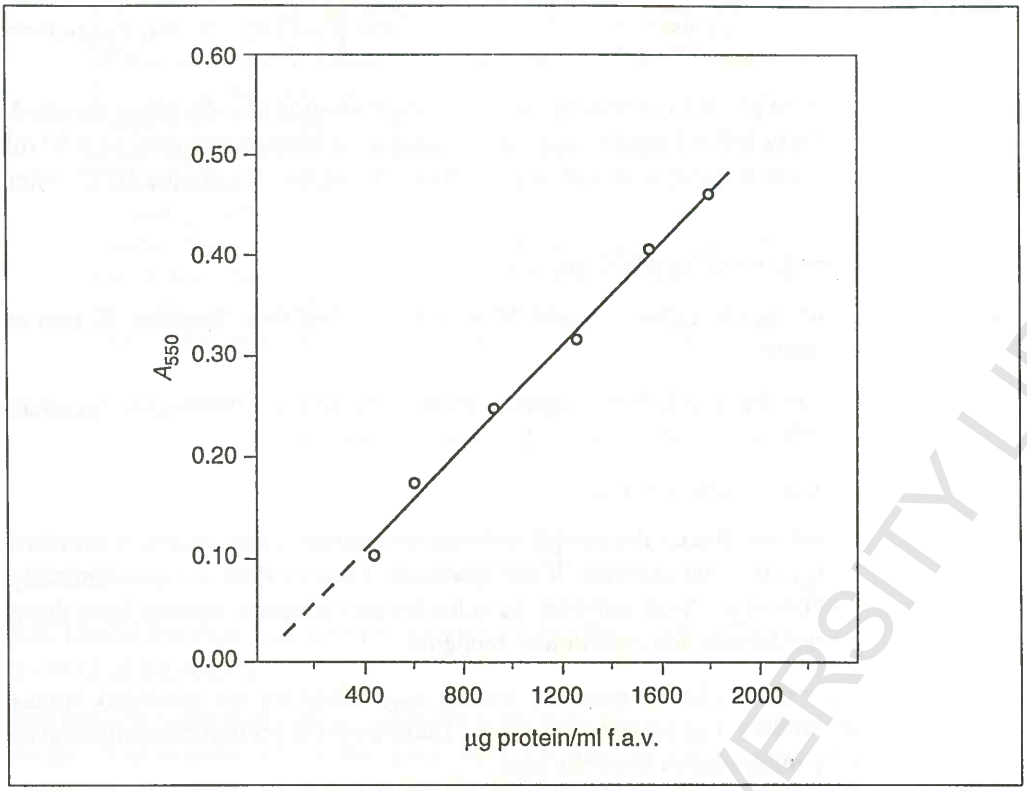

Figure 3.4.1 Biuret assay calibration plot using bovine serum albumin. Slope = 2.26×10^{-4} A_{550} (µg protein/ml f.a.v.)$^{-1}$ cm^{-1}.

HARTREE-LOWRY ASSAY FOR QUANTITATION OF TOTAL PROTEIN

BASIC PROTOCOL 2

The original Lowry method for total protein analysis was first described in one of the most cited papers in biochemistry (Lowry et al., 1951). The assay is a colorimetric assay based on cupric ions and Folin-Ciocalteau reagent for phenolic groups. The assay has been reinvestigated many times and sometimes improved. Most of these studies were designed to discern how interfering compounds distort the assay and how detergents solubilize otherwise insoluble proteins. The literature related to this assay was comprehensively reviewed by Peterson (1983). This protocol describes Hartree's version of the Lowry assay (Hartree, 1972). This version uses three reagents instead of five, produces more intense color (increased sensitivity) with some proteins, maintains a linear response over a larger concentration range (30% to 40% greater), is less easy to overload, and overcomes the reagent salt coprecipitation encounter with Lowry reagents. Finally, the reagents formulation offers some advantages in storage stability. It is somewhat less laborious than the original Lowry assay, and it maintains the sensitivity of the original.

Materials

Calibration standard: 300 µg crystalline BSA per ml in water
Buffer or solvent used to prepare the protein-containing sample
Sample containing protein at 100 to 600 µg/ml
Hartree-Lowry reagents A, B, and C (see recipes)

50°C water bath
Spectrophotometer and 1-cm cuvettes

1. Prepare a dilution series of calibration standard in the same buffer or solvent used to prepare the sample to give concentrations of 30 to 150 µg/ml.

BOGAZICI UNIVERSITY LIBRARY

Concentrations of albumin in the final assay volume (f.a.v.) of 5 ml may range from ~30 to 300 µg protein/ 5 ml f.a.v. to produce A_{650} readings from ~0.20 to 0.80.

2. Add 1.0 ml of the protein-containing sample, of each dilution of calibration standard, or of the buffer or solvent used to prepare the sample (reference standard) to 0.90 ml of Hartree-Lowry reagent A in separate test tubes. Incubate 10 min in a 50°C water bath.

3. Cool the tubes to room temperature.

4. Add 0.1 ml of Hartree-Lowry reagent B to each tube and mix. Incubate 10 min at room temperature.

5. Rapidly add 3 ml Hartree-Lowry reagent C to each tube and mix thoroughly. Incubate 10 min in a 50°C water bath, then cool to room temperature.

   The final assay volume is 5.0 ml.

6. Measure the net absorbance the sample, calibration standards, and reference standard at 650 nm (A_{650}) in 1-cm cuvettes. If the spectrophotometer does not automatically give net absorbance readings, subtract the value for the reference solution from those obtained for the sample and calibration standards.

7. Prepare a calibration plot by graphing the net A_{650} values for the standards versus protein concentration (µg protein/5 ml f.a.v.). Determine the protein concentration of the sample by interpolation from the plot.

   Plot the data as shown in Figure 3.4.2 and calculate the slope and its units. The slope of a calibration plot is proportional to the spectrophotometric absorption coefficient, and is a measure of the sensitivity of assay over the range indicated on the horizontal axis. Comparisons can be made with other measures, such as the weight absorption

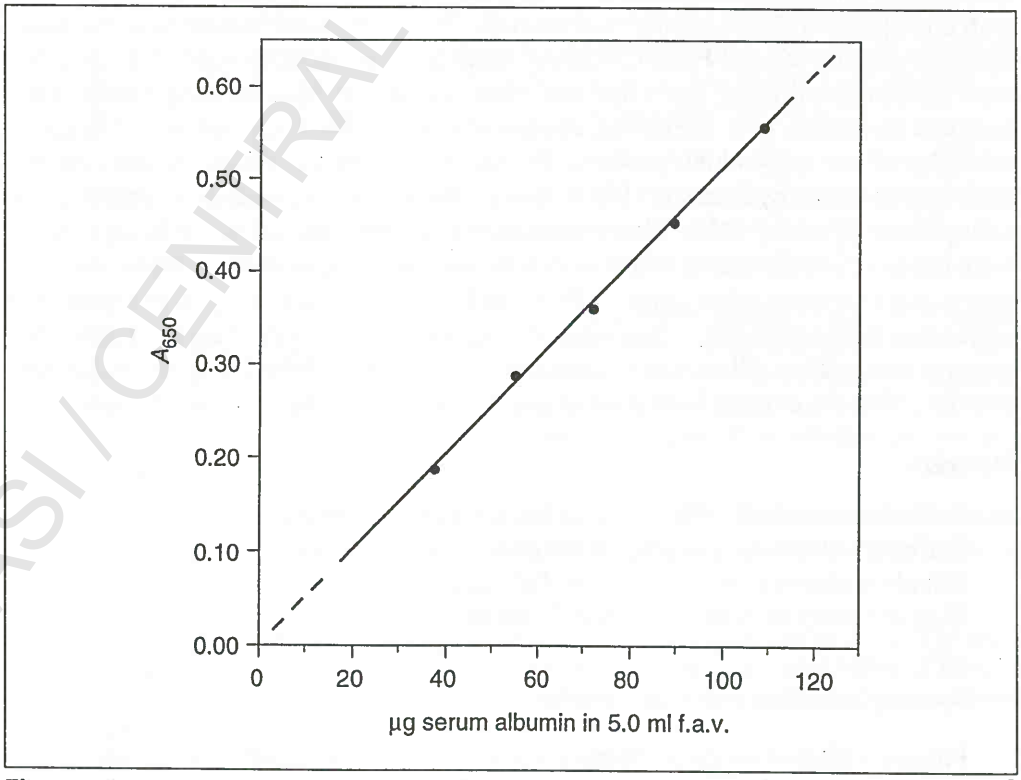

Figure 3.4.2 Hartree-Lowry assay calibration plot using bovine serum albumin. Slope = 2.5×10^{-2} A_{650} (µg protein/ml f.a.v.)$^{-1}$ cm^{-1}.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

coefficient ($E^{1\%}$) at the same wavelength. Units in the concentration factor in the denominator of $E^{1\%}$ are (dry g)/100 ml of final assay volume.

The units in this protocol, µg protein/ml final assay volume (f.a.v.), are used to permit comparison with values in the literature. It is not always clear whether the milligram or microgram amounts of protein indicated on the axes of these plots refer to the concentration in the input sample or to the final concentration after the addition of reagent(s). Differences in volumes of input versus final developed samples frequently involve dilution factors of 10^1 to 10^2. As an example, the $E^{1\%}$ values in the original report describing this procedure (see Table 4 in Lowry et al., 1951) are ~230 at 750 nm with 3-mm pathlengths. These values can be converted to units presented in this protocol by reconciling the two means for expressing the slopes (see Equation 3.4.1).

$$E^{1\%}_{1\ cm} = \frac{230\,A_\lambda}{\frac{g}{100\ ml\ f.\ a.\ v.} \times \frac{10^6\ \mu g}{g} \times cm} = \frac{2.3 \times 10^{-2} A_\lambda \times cm^{-1}}{\mu g/ml\ f.\ a.\ v.}$$

Equation 3.4.1

BICINCHINONIC ACID (BCA) ASSAY FOR QUANTITATION OF TOTAL PROTEIN

BASIC PROTOCOL 3

The bicinchinonic acid (BCA) assay for total protein is a spectophotometric assay based on the alkaline reduction of the cupric ion to the cuprous ion by the protein, followed by chelation and color development by the BCA reagent. Either a micro or a semimicro procedure, the latter generating a final assay volume of 2 or 3 ml, may be used; the semimicro procedure is most frequently used.

The BCA assay for total protein is somewhat variable: it has differing sensitivities in response to incubation time, incubation temperature, standard protein used for calibration, and other factors (Smith et al., 1985). Certain classes of compounds such as reducing sugars and ammonium ions interfere with the assay, sometimes severely. However, if interfering compounds are eliminated (e.g., by dialysis; see Support Protocol 2), the BCA assay has a good combination of sensitivity and simplicity, and it has some advantages over the Lowry technique (see Background Information).

Materials

Calibration standard: 1 mg BSA/ml
Buffer or solvent used to prepare the protein-containing sample
Sample containing protein
BCA reagent A/reagent B mix (see recipe)
Spectrophotometer and cuvettes

1. Prepare a dilution series of calibration standard in the buffer or solvent used to prepare the sample to cover the range 0.2 to 1.0 mg/ml.

2a. *For a 2.1-ml final assay volume:* Mix 100 µl of protein-containing sample, of calibrating standard, or of buffer used to prepare the sample (reference standard) with 2 ml BCA reagent A/reagent B mix in separate tubes.

2b. *For a 4.2-ml final assay volume:* Mix 200 µl of protein-containing sample, of calibrating standard, or of buffer used to prepare the sample (reference standard) with 4 ml BCA reagent A/reagent B mix in separate test tubes.

The final assay volume depends on the size of the available cuvettes.

BOU INST / BEIJING UNIVERSITY LIBRARY

3. Incubate the samples and standards 30 min at 37°C, then cool to room temperature.

4. Measure the absorbance of the sample, calibration standards, and reference standard at 562 nm (A_{562}). If the spectrophotometer does not automatically give net absorbance readings, subtract the values for the reference standard from those obtained for for the sample and calibration standards.

5. Prepare a calibration plot by graphing the net A_{650} values for the standards versus protein concentration (µg protein/ml f.a.v; see Fig. 3.4.3). Determine the protein concentration of the sample by interpolation from the plot.

Figure 3.4.3 shows a calibration plot prepared using BSA as the protein standard and a 2.1-ml final assay volume (f.a.v.). The slope of the plot is a measure of the sensitivity of the assay. The slopes of plots such as Figure 3.4.3 are also related to the absorption coefficients of the colored complexes. The units attached to the slope must take into account the extent of dilution and be consistent with the protocol used to develop the colored complexes. The value of the slope can be used to compare the different methods—e.g., Smith et al. (1985) compared the BCA and Lowry methods using BSA as calibrating protein. For the BCA method, the slope was 1.5×10^{-2} to 2.6×10^{-2} A_{562} (µg protein/ml f.a.v.)$^{-1}$ cm^{-1}; for the Lowry method, the slope was 1.6 to 2.3×10^{-2} A_{750} µg protein/ml f.a.v.)$^{-1}$ cm^{-1}.

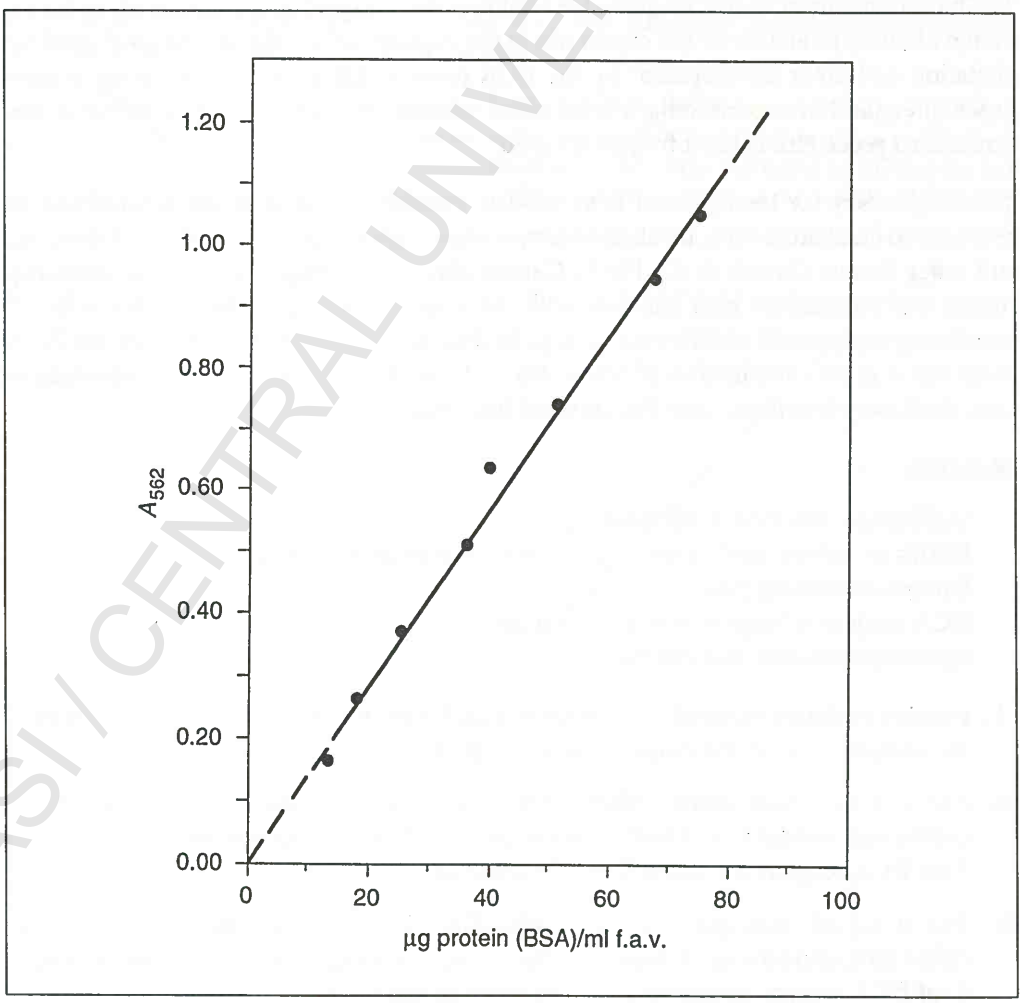

Figure 3.4.3 Bicinchinonic acid assay calibration plot using bovine serum albumin. Slope = 1.5×10^{-2} A_{562} (µg protein/ml f.a.v.)$^{-1}$ cm^{-1}.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

ACID DIGESTION–NINHYDRIN METHOD FOR QUANTITATION OF TOTAL PROTEIN

In this assay, proteins are hydrolyzed to amino acids with 6% sulfuric acid at 100°C. The hydrolysates are neutralized and the amino acids quantitated by ninhydrin derivatization and spectrophotometry at 570 nm (A_{570}). This method is resistant to interference by phenolic and related compounds that may affect Folin reaction–dependent analyses.

Individual amino acids do not produce equal "color yields" upon reaction with ninhydrin. However, most proteins—except those with unusual compositions such as high hydroxyproline and proline (collagens), extraordinary sulfur contents (cysteine; e.g., alcohol dehydrogenase and thionein), or densely glycosylated proteins (e.g., invertase and glycophorin)—give reasonable results using leucine as a calibration standard. Ammonium ion generates strong color with ninhydrin, nearly equivalent to that produced by leucine. However, TCA precipitation of the proteins prior to acid hydrolysis will remove NH_4^+, which will be left in the supernate (see Support Protocol 3).

Materials

H_2SO_4
NaOH
Sample containing protein
Calibration standard: 0.2 mg/ml leucine, diluted ½ to 1/20
Ninhydrin reagent (see recipe)
Isopropanol diluent: 50% (v/v) isopropanol in water

Heat-sealable tubes
100°C water bath

1. Based on the percentage H_2SO_4 (e.g., 6%) to be used in this assay, determine the volume of NaOH required to neutralize the reaction.

   For example, 6% H_2SO_4 is ~2.3 N (H^+), so it would take ~15.3 ml of 6% (w/v) NaOH (1.5 N) to completely neutralize 10 ml of 6% H_2SO_4.

   In this protocol, % H_2SO_4 refers to a v/v dilution of concentrated H_2SO_4.

   The total volume of the reaction mixture after the addition of acid, base, and ninhydrin reagent to a protein solution containing 10 to 20 mg protein should be close to 3 but no more than 6 ml. If necessary, use more concentrated acid and base solutions to prevent excessive dilution of the sample.

2. In a heat-sealable tube, add H_2SO_4 to an 0.02- to 0.05-mg protein sample to give a final concentration of 3% acid. Seal the tube under a nitrogen blanket (see Support Protocol 1) and incubate 12 to 15 hr (overnight) at 100° to 105°C.

   Protein in aqueous solution may be used directly if it does not contain many additional amino acids and oligopeptides. If the sample is dilute or contains contaminants or interfering compounds, the protein can be precipitated and concentrated using TCA (see Support Protocol 3). After the supernatant is removed, 3% H_2SO_4 can be added directly to the TCA precipitate for hydrolysis.

3. Open the tube and add the appropriate volume of 6% NaOH, as determined in step 1, to neutralize the H_2SO_4 used in hydrolysis.

4. Add 2 ml ninhydrin reagent to the neutralized sample, and to equal volumes of diluted calibration standards, and of the buffer (reference standard) in separate test tubes. Incubate the mixture 20 min in 100°C (boiling) water bath. Cool to room temperature.

   Calibration and reference standards should be light blue, samples a darker purplish blue. Very dark samples should be diluted by a factor of 2 to 5 with isopropanol diluent

BOSTON COLLEGE UNIVERSITY LIBRARY

(dilute all standards to the same extent). Dilution may be performed after incubation with the reagent, and it is not necessary to repeat the assay in such cases.

6. Measure the net absorbance of sample and calibration and reference standards at 570 nm (A_{570}). If the spectrophotometer does not automatically give net absorbance readings, subtract the value for the reference standard from those obtained for sample and calibration standards.

   The absorbance of a sample dominated by hydroxyproline and proline may be read at 440 nm; a separate set of calibration standards should be prepared with these amino acids.

7. Prepare a calibration plot by plotting the adjusted values versus protein concentration (µg protein/ml f.a.v.). Determine the protein concentration of the sample by interpolation from the curve.

   The slope of ninhydrin color yield (A_{570}) with most amino acids is 20 to 25 A_{570} µmol amino acid/ml f.a.v.$^{-1}$ cm^{-1}. As a general guide, use 0.02 to 0.05 mg protein per assay.

SUPPORT PROTOCOL 1

HEAT SEALING GLASS TUBES

For acid hydrolysis at 100° to 104°C, air (oxygen) should be excluded and evaporation should be prevented by carrying out the hydrolysis in sealed tubes. Ordinary glass test tubes, ~10 to 12 mm diameter and 10 cm long, can be used for this purpose. Figure 3.4.4 summarizes the procedure.

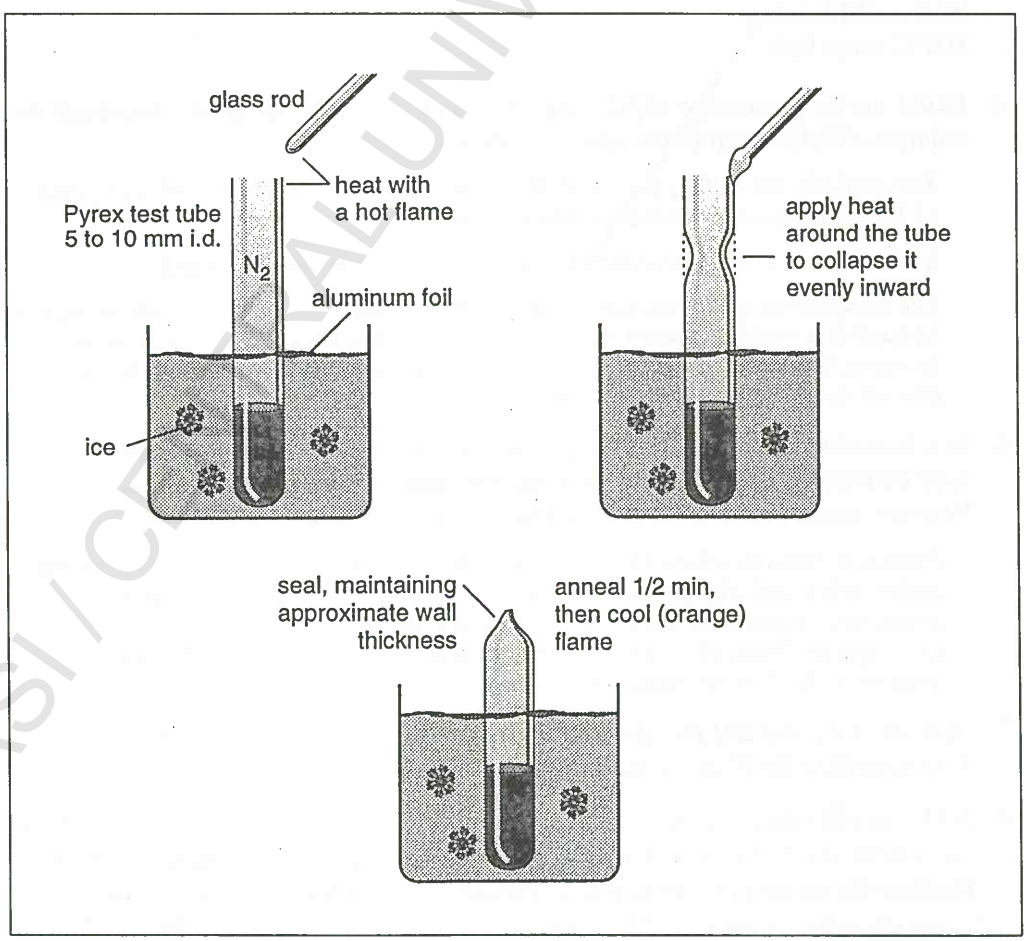

Figure 3.4.4 Heat sealing test tubes for hydrolysis.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Materials

Pyrex glass test tube, 10 to 12 mm diameter × 10 cm long
Nitrogen gas
Glass rod
Gas-oxygen flame source
Triangular file

1. Set a Pyrex test tube containing sample to be hydrolyzed in ice and briefly blanket the tube with nitrogen gas.

   CAUTION: *Adjust the force of the nitrogen stream carefully to avoid splashing the acid solution out of the tube or up the sides of the tube.*

2. Using a gas-oxygen flame, fuse a small glass rod to the lip of the test tube to act as a handle.
3. Use the flame to apply heat around the body of the tube, ~2 cm below the lip until the tube softens and collapses.
4. Slowly withdraw the "handle" and the scrap upper end, maintaining test tube wall thickness around the seal.
5. When the seal is fused, reduce the flame temperature down to an orange, then a red flame and continue to flame the seal for ~½ min.

   This should anneal the glass. Do not build a thick seal, which is likely to crack, or draw out the seal so that it becomes thin and likely to blow out.

6. After acid hydrolysis, break the tubes open as follows. First make a deep scratch with a sharp triangular file, about one-third of the way around the tube. Then heat a glass rod until it is white hot, wet the scratch, and apply the white-hot glass rod to the scratch.

   This quite reliably cracks the tube all round and the top easily lifts off.

ULTRAVIOLET ABSORPTION TO MEASURE TOTAL PROTEIN

BASIC PROTOCOL 5

Proteins contain tyrosine and tryptophan side chains that are fairly strong absorbers of light in the 275- to 280-nm (ultraviolet) region. Consequently, after suitable dilution to produce on-scale absorbance readings, total protein can be estimated from UV absorbance spectra using quartz or fused silica cuvettes. Phenylalanine, which has an aromatic side chain, is only weakly absorbing and is usually neglected for most purposes. Weight absorption coefficients, $E^{1\%}$ values (concentration of protein in dry grams per 100 ml volume or weight/volume percent) range between ~3 and 30 A_{280} units $(gm/100\ ml)^{-1}\ cm^{-1}$ for most proteins. A useful survey of $E^{1\%}$ values for individual proteins at 275 to 280 nm is available in Sober (1970). If the molecular weight of proteins is known, the molar absorption coefficient, ε_λ in moles/liter is related to the $E^{1\%}$ values at the same wavelength, by Equation 3.4.2.

$$10\ \varepsilon_\lambda = E_\lambda^{1\%} \times \text{molecular weight}$$

Equation 3.4.2

Molar absorption coefficients can be calculated from amino acid composition based on tyrosine and tryptophan contributions to the total molecule. The $\varepsilon_{275\text{-}280}$ values for tyrosine (in neutral or acidic solution) and for tryptophan are close to 1470 and 5700 absorbance

B.C.U. Int. Z.[illegible] CHILE
BCU IAS CENTRAL UNIVERSITY LIBRARY

units M^{-1} cm^{-1}, respectively. There are minor variations in these values depending on the peptide and the solvent (Bencze and Schmid, 1957).

For example, an 0.04% to 0.12% solution of protein having 4 to 12 tyrosine groups, 2 to 6 tryptophans, and an ε_{280} value of ~8, should have an A_{280} of ~0.2 to 1 with a 1-cm path length cuvette. Hence UV absorption around the 280-nm band provides a fairly sensitive, convenient means for detecting and quantitating pure proteins or mixtures of pure proteins having concentrations in the range of 0.1 to 1 mg/ml.

Materials

Protein sample, pH <8
Fused-silica or quartz cuvettes

1. Turn on the spectrophotometer, set the wavelength to 280 nm, and allow it to warm up 30 min.
2. Dilute the protein sample, if necessary, to give an A_{280} between 0.2 and 1.

   Some spectrophotometers may give precise measurements of A_{280} up to 2 absorption units but in general, conditions and concentrations should be adjusted so the instrument is not forced to read absorbances >0.9 to 1.0.

3. Read the absorbance of sample and reference standard (buffer or solvent) at 280 nm in fused-silica or quartz cuvettes.

   Glass and plastic cuvettes are opaque below the near UV range, ~350 mm.

   A complete UV absorption spectrum, ~230 or 240 nm to >310 nm, may be very helpful for detecting interfering compounds. For a solution of one or more pure proteins at acid pH, there should be a deep trough at 250 nm, a peak around 275 to 280 nm, and very little absorption above 310 nm, unless the proteins contain cofactors or prosthetic groups.

4. If necessary, dialyze or precipitate the sample to remove contaminants and interfering compounds and reread the A_{280}.

BASIC PROTOCOL 6

COOMASSIE DYE–BINDING ASSAY (BRADFORD ASSAY) TO MEASURE TOTAL PROTEIN

Coomassie dye (Brilliant blue G250) binds to protein molecules in acid pH by two means. The triphenylmethane group binds to nonpolar structures in proteins, and the anion sulfonate groups interact with protein cationic side chains (e.g., arginine and lysine side chains) in acid pH (Lovrien et al., 1995). The color change produced when the dye binds to proteins provides a measure of total protein, which is quite sensitive in the case of albumin and certain globular proteins (Bradford, 1976; Sedmak and Grossberg, 1977). The Coomassie dye-binding assay, or Bradford assay, also responds to some interfering substances which are generally unknown unless specifically tested for (Van Kley and Hale, 1977; Kirazov et al., 1993). Nevertheless, because of its apparent simplicity and sensitivity towards many proteins, the Bradford assay is popular and widely used. Using bovine serum albumin (ideally well behaved) to calibrate the Bradford assay produces a calibration plot with a slope of 4.5 to 5.5 × 10^{-2} (μg protein/ml f.a.v.)$^{-1}$cm^{-1}. Hence, it is somewhat more sensitive, by a factor of roughly two or three, than the values generally quoted for Lowry, Hartree-Lowry, or BCA assays (see Fig. 3.4.2 and see Table 3.4.2).

BCU IAS CENTRAL UNIVERSITY LIBRARY

Materials

Calibration standards: 1.5 mg/ml BSA and 1.5 mg/ml lysozyme
Buffer or solvent used to prepare the protein-containing sample
Sample containing protein
Coomassie dye reagent (see recipe) *or* commercial Coomassie reagent (Bio-Rad, Pierce)

1. Prepare a dilution series of calibration standards in the buffer or solvent used to prepare the sample to cover the range 150 to 750 µg protein/ml.

   Depending on the kind of protein being measured, it may be useful to calibrate with various proteins including proteins related to or even a purified preparation of the protein being analyzed. For example, if collagen is the analyte, various collagens, high-glycine-hydroxyproline polymers, should be used as calibrating standards. Bovine serum albumin (BSA) is often used as a calibration standard, but it has greater general dye-binding capacity than most proteins.

2. Add 100 µl of protein-containing sample, calibration standard, or of buffer used to prepare the sample (reference standard) to 5 ml Coomassie dye reagent. Mix. Incubate 10 min at room temperature.

   The ratio of sample to reagent may range from 1:20 to 1:50 (v/v). A micro assay can be performed using 5 to 10 µl sample in 250 to 500 µl Coomassie dye reagent.

   If a commercially prepared Coomassie reagent is used, follow the manufacturer's instructions.

3. Measure the absorbance of the sample, calibration standards, and reference standard at 595 nm (A_{595}). If the spectrophotometer does not automatically give net absorbance readings, subtract the values for the reference standard from those obtained for the sample and calibration standards.

4. Prepare a calibration plot by graphing the net A_{595} values for the standards versus protein concentration (µg protein/ml f.a.v.). Determine the protein concentration of the sample by interpolation from the plot.

   At maximal sensitivity (with BSA as a calibration standard) the Coomassie dye-binding assay produces a calibration plot with a slope (sensitivity) of ~4×10^{-2} A_{595} (µg/ml f.a.v.)$^{-1}$ cm^{-1} and falls to a third or half of that value with less responsive proteins.

DRY WEIGHT DETERMINATION TO MEASURE TOTAL PROTEIN

BASIC PROTOCOL 7

Drying a protein-containing sample in a 104° to 106°C oven for a few hours removes water and volatile materials. The sample is then weighed on a balance to measure the aggregate weight of protein plus whatever nonvolatile material remains, such as salts and many buffers.

Materials

Protein sample
Small weighing bottle or beaker
104° to 106°C oven

1. Dry a small weighing bottle or small beaker by heating it 10 min in a 104° to 106°C oven.

2. Cool the weighing container in a desiccator 10 min.

3. Weigh the container on a balance to the nearest 0.1 mg (tare weight).

BCU IRSI / CENTRAL UNIVERSITY LIBRARY

4. Add a 0.5- to 3-ml sample of protein solution to the container.

   Buffer salts, polysaccharides, the salt forms of amino acids, and high molecular weight pigments and sugars may not be driven off in a 4- to 6-hr drying cycle (see step 5). They should be removed from the sample by dialysis, ion-exchange chromatography, or precipitation before it is dried (see Support Protocols 2 and 3).

5. Dry the sample and container 4 to 6 hr (or overnight) at 104° to 106°C.

   Usually it is not necessary to carry out more than one cycle of drying, cooling, and weighing to approach a constant weight.

   Overnight drying is required for samples to 5 to 10 ml.

6. Cool the container and reweigh it (dried weight).

7. Calculate the dry weight of the sample as: dry sample weight = dried weight of container and protein – tare weight.

   The first dry weights measured after 6 hr usually remain constant, but if volatile salts such as ammonium chloride and ammonium formate are present, the sample may have to be dried longer or for more cycles to completely drive them off.

   Dry weight is reliable to within ~3% for net weights of 2 to 4 mg protein and to within 1% to 2% for ≥5 mg protein.

SUPPORT PROTOCOL 2

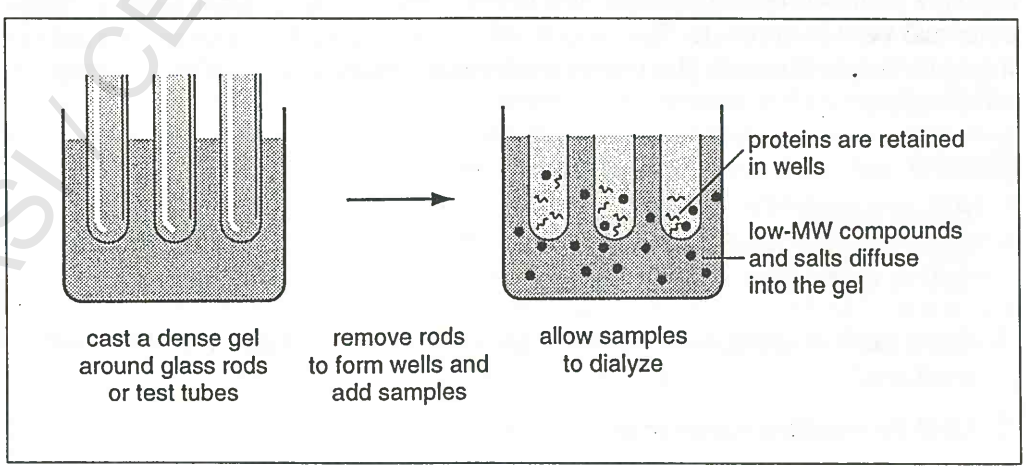
GEL DIALYSIS OF PROTEIN SAMPLES

This protocol describes a simple method for dialyzing small interfering molecules and salts away from protein samples using an agarose or polyacrylamide gel (see Fig. 3.4.5; Freifelder and Better, 1982). Somewhat dense, well cross-linked gels are used to keep proteins from penetrating the gel while unwanted salts and low-molecular-weight compounds diffuse (are "dialyzed away") into the gel. This is a micro to semimicro method, an alternative to conventional dialysis (Craig, 1967), and to the use of small pressure-membrane disposable kits or microcentrifuge filtration units with MWCO values of 5,000 to 10,000.

Materials

Polyacrylamide gel (*UNIT 10.1*)
Sample containing protein

Small glass rods or test tubes
Beaker



proteins are retained in wells
low-MW compounds and salts diffuse into the gel
cast a dense gel around glass rods or test tubes
remove rods to form wells and add samples
allow samples to dialyze

Figure 3.4.5 Dialysis by out-diffusion of low-molecular-weight compounds into gels cast in small cavities (Beyer, 1983).

BCU IASI CENTRAL UNIVERSITY LIBRARY

1. Suspend small glass rods or test tubes inside a beaker.

   The glass rods or test tubes are used to form wells that will hold the protein sample. Use a size that will create a well of sufficient volume to hold the sample.

2. Prepare a 12% to 15% polyacrylamide gel cross-linked with 0.8% to 1.5% bisacrylamide and pour it into the beaker to a depth that will provide wells of sufficient volume to hold the protein sample. Allow the gel to polymerize. Remove the glass rods or test tubes.

   In this procedure, the intent is to prevent the protein from entering the gel. Alternatively, 2% to 5% agarose gels may be used.

   If the gels are to be stored, fill them with water to prevent drying. Remove the water and blot out any excess before adding a protein sample.

3. Add the protein sample to the well and let stand 30 min to 1 hr at room temperature.

   If the wells have a diameter >5 mm, dialyze for 1 to 2 hr or longer. The rate of dialysis is temperature dependent, so dialysis should be carried out at room temperature or higher if it does not adversely affect the protein.

4. Use a pipet to transfer the dialyzed protein sample from the well to a clean test tube suitable for the selected total protein assay.

TRICHLOROACETIC ACID PRECIPITATION OF PROTEIN SAMPLES

SUPPORT PROTOCOL 3

Trichloroacetic acid (TCA) precipitation can be used to precipitate proteins away from TCA-soluble, low-molecular-weight compounds that may interfere with assays for total protein. The procedure may also be used to concentrate protein from a dilute aqueous solution.

Add 10% (w/v) TCA to a protein sample to give a final concentration of 3% to 4% (v/v). Let stand 2 to 5 min at room temperature. Remove the supernatant and resuspend the precipitate in neutral buffer or alkali, depending on the method for further analysis.

If the sample is to be acid hydrolyzed (see Basic Protocol 4), carry out TCA precipitation in the heat-sealable tube, remove the supernatant, and dissolve the precipitate in 3% H_2SO_4.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

BCA reagent A

1 g 4,4′-dicarboxy-2,2′-biquinoline, disodium salt (Na_2BCA; Pierce or Sigma; 26 mM final)
2 g $Na_2CO_3 \cdot H_2O$ (0.16 M final)
160 mg disodium sodium tartrate (7 mM final)
0.4 g NaOH (0.1 M final)
0.95 g $NaHCO_3$ (0.11 M final)
100 ml H_2O

After mixing and dissolving the components, adjust the pH to 11.3 ± 0.2, using solid NaOH to increase pH or $NaHCO_3$ to decrease pH. Store this alkaline reagent in a plastic container 1 to 3 weeks at room temperature, longer at 4°C.

Only the disodium salt of Na_2BCA is soluble at neutral pH; the free acid is not readily soluble, even in alkali.

BCIT LIBRARY / CENTRAL UNIVERSITY LIBRARY

BCA reagent B

4 g $CuSO_4 \cdot 5H_2O$ (16 mM final)
100 ml H_2O
Store up to a few months at room temperature

BCA reagent A/reagent B mix

Mix 50 vol BCA reagent A with 1 vol BCA reagent B (see recipes). Prepare only sufficient mix for a few days' work because the mixture is not stable.

BCA reagent A/reagent B mix is light apple-green in color.

Biuret reagent

1.5 g $CuSO_4 \cdot 5H_2O$ (6 mM final)
6 g sodium potassium tartrate tetrahydrate ($C_4H_4KNaO_6 \cdot 4\ H_2O$, Rochelle salt; 21 mM final)
300 ml 10% (w/v) NaOH (0.75 M final)
Preboiled, cooled H_2O to 1 liter
Store at room temperature in plastic bottles

The water should be preboiled and cooled to remove dissolved CO_2.

Biuret reagent ordinarily is stable for several months. If a black color (due to cupric oxide) develops, discard the reagent.

CAUTION: *Discarded reagent and assay samples may be stored in open plastic buckets in a chemical fume hood to reduce volume (evaporate off water). The salts, especially copper, should be disposed of as hazardous waste.*

Coomassie dye reagent

100 mg Coomassie brilliant blue G250 [0.01% (w/v)]
50 ml 95% ethanol (5% final)
100 ml 85% phosphoric acid (8.5% final)
H_2O to 1 liter
Filter through Whatman no. 2 filter paper
Store up to 1 month at room temperature in a glass container

Coomassie brilliant blue G250 is available from Sigma (as brilliant blue G1), Bio-Rad, Pierce, and others.

Hartree-Lowry reagent A

2 g sodium potassium tartrate·4 H_2O (Rochelle salt; 7 mM final)
100 g Na_2CO_3 (0.81 M final)
500 ml 1 N NaOH (0.5 N final)
H_2 to 1 liter
Store 2 to 3 months at room temperature in a plastic container

Hartree-Lowry reagent B

2 g sodium potassium tartrate·4 H_2O (0.07 M final)
1 g $CuSO_4 \cdot 5H_2O$ (0.04 M final)
90 ml H_2O
10 ml 1 N NaOH
Store 2 to 3 months at room temperature in a plastic container.

Hartree-Lowry reagent C

Dilute 1 vol Folin-Ciocalteau reagent (Sigma) with 15 vol water.

Prepare this solution daily in 16-ml quantities or multiples thereof. Do not adjust the pH.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Ninhydrin reagent

Solution 1:

0.2 M citrate buffer, pH 5.0
21 g citric acid monohydrate (reagent grade; 0.22 M final)
200 ml 1 N NaOH (0.4 N final)
H_2O to 500 ml
Store at 4°C

Solution 2

0.8 g $SnCl_2 \cdot 2H_2O$ (7 mM final)
500 ml 0.2 M citrate buffer, pH 5.0 (Solution 1; 0.1 M final)

Solution 3

20 g ninhydrin, crystalline [Sigma; 4% (w/v) final]
500 ml 2-methoxyethanol (methyl cellosolve)

Working solution: Mix 500 ml Solution 2 and 500 ml Solution 3. Purge with nitrogen and store in dark bottles at 4°C.

The quantities of reagents can be scaled down.

Methyl cellosolve (2-methoxyethanol) often forms peroxides that need to be removed, e.g., by refluxing over tin metal and distilling. Alternatively, it can be purchased protected under nitrogen (e.g., from Aldrich). In any case, ninhydrin solutions in methyl cellosolve should be purged briefly with nitrogen after each use to exclude air.

CAUTION: *Methyl cellosolve has a boiling point of 124°C and is rather toxic, though not very volatile. Large quantities should be handled in a chemical fume hood.*

CAUTION: *Ninhydrin solution stains everything with an intense purple color. Always wear gloves and a lab coat when mixing and transferring ninhydrin solutions. Avoid spills. If skin becomes stained, wash with soap and water several times per day; color will persist for several days.*

COMMENTARY

Background Information

Many assays for quantitating total protein exist. Several are reliable and straightforward. How to chose the most suitable or optimal method is a recurring problem; the solution frequently requires the use of more than one method or protocol. A good strategy is to compare the results of two methods, such as A_{280} measurements and one of the copper-based chromogenic methods—assays that rely on different chemical properties. Very large differences in total protein estimates from two or more methods occur with crude preparations from bacterial cells, cell cultures, tissues, and food extracts, all of which may be laden with interfering substances. The principle question is often not how sensitive a particular protein assay happens to be, but rather how the assay is affected by interfering substances. The primary concern is how to maneuver around the interfering compounds or how to eliminate them altogether, using analytical protocols to follow the progress. Methods for dealing with some of the more common interfering substances are discussed below.

Individual total protein analytical methods commonly disagree with one another by as much as 5% to 20% even in the case of a well-behaved protein not laden with interfering compounds. Disagreement in the case of crude samples may be much greater. There are two general ways to deal with such discrepancies. The first is to remove interfering compounds that are likely to upset one, or perhaps both, analyses, or to resort to a third method, such as biuret analysis, if there is enough sample to resolve the differences. The second and ultimate is to conduct total nitrogen analysis, e.g., by the Kjeldahl method or modern versions of it. It is a generally reliable practice to assume that all proteins and polypeptides contain very close to 16.5% nitrogen by weight, so multiplication of the weight of nitrogen obtained from Kjeldahl analysis by a factor of 6.0 should provide a valid benchmark measure of the weight of protein in an ammonium salt–free sample.

The protocols and related commentaries in this unit describe specific, frequently used methods for quantitating total protein. How-

BOSTON CENTRAL UNIVERSITY LIBRARY

ever, this field is still evolving. *Analytical Biochemistry* frequently contains reports of new analytical methods, variants of existing methods, and methods for removing interfering compounds.

Recording and reporting data for total protein analysis

Calibration curves for spectrophotometric (colorimetric) assays for total protein are almost always plotted with the vertical axis in units of absorbance at the optimum wavelength (A_λ), which usually ranges between 0 and 1.00, or 0 and 2.0, depending on the spectrophotometer. The horizontal axis is usually labeled in units of protein such as µg or mg, often without specifying the related volume—the volume of sample introduced into the assay or the concentration per milliliter of sample or per milliliter of total assay volume. If a 0.50-ml sample is analyzed in a colorimetric assay that adds 3 to 6 ml of reagents, there is a >10-fold concentration difference involved. For this reason, it is very important to be clear and specific in defining the appropriate volume units for the values on the horizontal axis. Clear specification of units for calibration curves is also important because the numerical value of the slope is a direct measure of the sensitivity of the method and a reflection of the molecular composition of the calibrating protein(s). Molar absorption coefficients at specified wavelengths (ε_λ) are defined in Equation 3.4.3, where l is cuvette pathlength in cm, c is the molar concentration of the chromogen (moles liter^{-1}), and A_λ is the absorbance as read from the spectrophotometer. In most cases, path length $l = 1$ cm.

$$\varepsilon_\lambda = \frac{A_\lambda}{c \times l}$$

Equation 3.4.3

Because spectrophotometry-based total protein analyses produce calibration plots of A_λ versus concentration (c), the slopes of the plots are either directly equal to molar absorption coefficients (if c is in units of molarity) or directly proportional to molar absorption coefficients (if other units are used for the horizontal axis). A well-characterized pure protein (e.g., bovine serum albumin, BSA) used for calibration should produce a calibration curve with a slope (absorption coefficient) that is reasonable based on the composition of the protein for the chromogen or prochromogen. BSA has close to 18 phenolic (tyrosine) groups per protein molecule. Calibration of a procedure such as the Folin assay that depends on phenolic side chains should respond at least semiquantitatively to the protein's composition as well as its concentration variation. Folin assays for phenolic (and cresol) compounds produce ε_{700} values in the range 7500 to 8500 M^{-1} cm^{-1}; the Folin "color yield" for BSA should be within ±5% of the value for an equivalent number of cresol side chains.

Careful performance of total protein assays and recording of the results are helpful for two reasons. First of all, information from the calibration curve can be compared to known absorption coefficients for purified or partially purified proteins to evaluate the accuracy of the assay. Second, the results can be used as a guide in planning additional experiments to minimize the amount of sample protein required for analysis. Even approximate calculations of the amount of protein, numbers of tyrosine side chains in individual proteins, useful dilution ranges, or amounts of lyophilized protein to use can be helpful in the planning stages and initial benchwork.

It is not necessary for the horizontal axis to be plotted in units of molarity. However, it is desirable both for planning and for cross-checking results that units include a clear statement of volume so they can be readily converted to other units as needed for reporting and planning. One appropriate unit is µg or mg/ml of final assay volume (per ml f.a.v.), which specifies the concentration of the analyzed protein in the operational volume of a solution for spectrophotometric reading after the sample, reagents, and diluents have all been combined.

Table 3.4.2 lists the slopes of calibration curves, equivalent to absorption coefficients and assay sensitivities, for proteins and sugars in some commonly used assays. For some total protein assays, it is a good strategy to monitor sugars in parallel to evaluate removal of interfering compounds. Details for total sugar and reducing sugar assays are outlined in Lovrien et al. (1987) and references therein.

Proteins are frequently investigated and put into large-scale production and use before their molecular weights are known. However, their dry weights may be available. Hence the relationship between molar absorption coefficients (ε_λ) and weight absorption coefficients ($E^{1\%}$) at a stated wavelength is useful for converting data using Equation 3.4.2. The molar absorption coefficient and the weight absorption coefficient are related to absorbance readings at

Copper ion–dependent assays for total protein

The biuret, Lowry, and bicinchinonic acid (BCA) assays are all dependent on copper ions—cupric and cuprous ions. Prochromogenic reagents used in each copper-based assay—Folin reagent, Folin-Ciocalteau, and BCA reagent—depend on the extent of reduction of cupric ion (Cu^{2+}) to cuprous ion (Cu^{+}) to develop their color (Smith et al., 1985). The brilliant color that BCA reagent develops is the result of formation of a complex with Cu^{+} but not Cu^{2+}. In turn, the amount of Cu^{+} produced depends on the amount of protein present, so color development is a measure of the amount of protein (see Fig. 3.4.6).

Compounds that affect either cupric or cuprous ion chemistry will interfere with the assays. In the BCA assay, the reagent chelates the cuprous ion. In the biuret assay, alkaline cupric ion interacts with polypeptide chains. The biuret reaction which is based on the interaction of the cupric ion with the imide form of the polypeptide in strong base to ionize the proton off the polypeptide amide group, may be a precursor to more strongly chromogenic, later-developed color-producing reactions. Aliphatic amines and ammonia or ammonium ion are strong ligands for copper, at least for Cu^{2+}. Reducing agents such as glucose can certainly be expected to interfere with these assays. Proteins rich in disulfide and sulfhydryl groups such as keratin interfere because reduced sulfur compounds powerfully bind to and reduce Cu^{2+}. Cupric ions in general are avid coordinating metals for foreign compounds, precipitating with them or becoming reduced by them. Large concentrations of ammonium sulfate and some of the phosphates used in purification schemes interfere with cupric ion–based chemistries. A list of interfering compounds, many

of them used as buffers or found as metabolites in protein technology, is presented in Smith et al. (1985) and briefly summarized in Table 3.4.3.

Biuret assay

The biuret assay (see Basic Protocol 1) is periodically reinvestigated, using different formulations for the reagents and different proteins as calibrating standards. There are a number of modifications for the method scattered through the literature (Goshev and Nedkov, 1979). Some of these recommend the addition of KI, ~5 g per liter of reagent (Layne, 1957). Differences in apparent slopes from laboratory to laboratory may occur because of varying amounts of inert materials such as NaCl or water from incompletely dry proteins used for calibration. The average slope for the biuret assay, obtained using several globular proteins as calibration standards, is $\sim 2.5 \pm 0.3 \times 10^{-4}$ A_{550} (μg protein/ml of f.a.v.)$^{-1}$ cm^{-1}, about 100 times smaller than the Hartree-Lowry and BCA assays.

A perennial question in total protein analysis is the choice of calibration standard: should the protein be a purified sample of the protein under study or will BSA suffice? Although it is true that some total protein assays, notably UV-based A_{280} assays, are dependent on the amino acid composition of the protein, biuret chemistry is based on polypeptide structure, not the composition of side chain residues. Accordingly biuret assays are rather independent of the protein used as the calibration standard.

The Hartree-Lowry assay

The original Lowry method for total protein analysis (Lowry et al., 1951) has been reinves-

PCU IASC CENTRAL UNIVERSITY LIBRARY

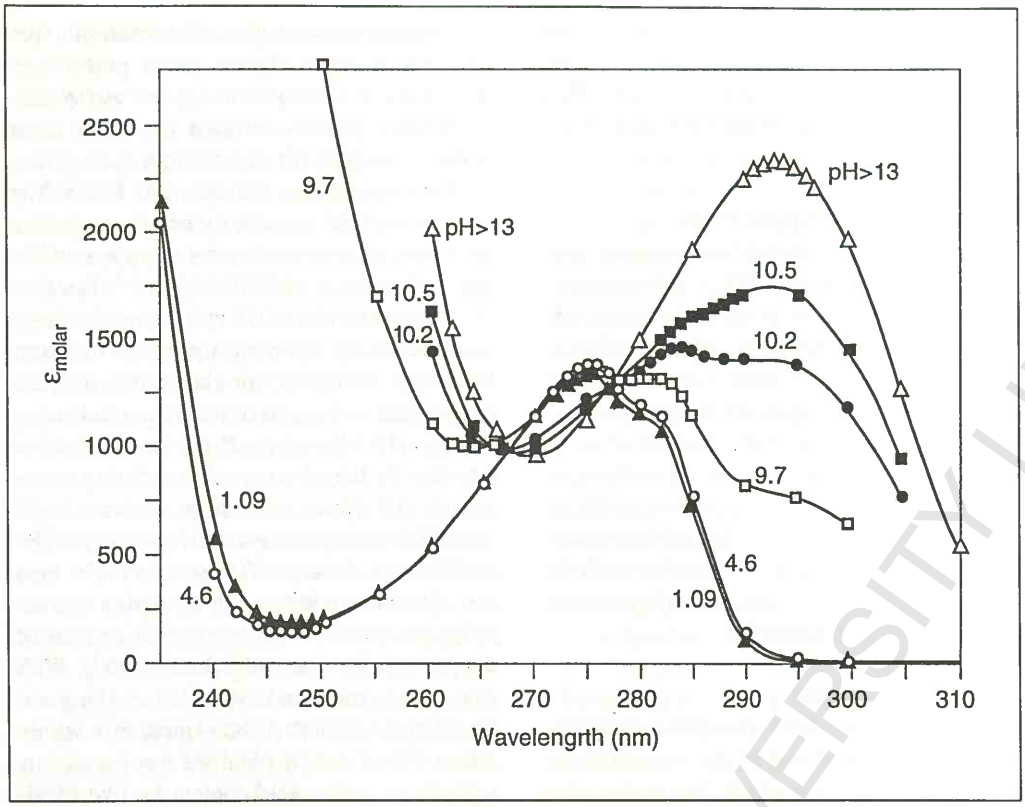

Figure 3.4.7 Absorption spectra of glycyl-L-tyrosine as a function of pH (Craig, 1967).

tigated many times to evaluate the effects of interfering compounds and the ability of detergents to solubilize otherwise insoluble proteins (reviewed by Peterson, 1983). The Hartree-Lowry assay (see Basic Protocol 2) yields linear results over a wider range of protein concentration, maintains the sensitivity, and is superior in the formulation of reagents (Hartree, 1972).

The bicinchinoinic acid assay

The bicinchinonic acid (BCA) assay (see Basic Protocol 3 and Fig. 3.4.6) developed by P.K. Smith et al. (1985) uses cupric ion in a biuret reaction with proteins in a strong base. The biuret reaction produces cuprous ion from cupric ion, and the cuprous ion is chelated with the BCA reagent. The Cu^{+}-BCA chelate is brilliantly colored with an absorption peak, λ_{max}, at 562 nm. Therefore, A_{562} is directly dependent on protein concentration, when the reaction conditions outlined by Smith et al. (1985; see Basic Protocol 3) are maintained.

The BCA method compares favorably with the older Lowry or Hartree-Lowry methods in sensitivity and convenience. The sensitivity of the BCA assay can be increased somewhat by using a higher concentration of the BCA reagent (i.e., of bicinchinonic acid disodium salt). However, the BCA reagent is rather expensive, and the fractional increase in sensitivity may not be worth the increase in cost.

The BCA assay is less susceptible than other assays to interference by a number of detergents. For this reason the BCA assay is sometimes favored with detergent-loaded samples, e.g., membrane and cellular proteins extracted by detergent solubilization. On the other hand, the BCA assay is susceptible to interference by reducing sugars, and even by ostensibly nonreducing sugars such as sucrose (because sucrose releases reducing sugars on partial hydrolysis; Spies, 1957). Some experimental systems use 10^{-3} to 10^{-4} M sulfhydryl reagents to protect proteins. These reagents can contain significant quantitites of reduced sulfhydryl reagents such as mercaptoethanol that react with cupric ion. Dialysis or other methods for removing organic –SH compounds from the sample may be required.

In order to avoid interfering substances in general, and also to increase protein concentrations, powerfully precipitating agents such as TCA (trichloroacetic acid) may be useful (Annand and Romeo, 1976; Beyer, 1983; also see Support Protocol 3). Most proteins in even dilute solution are quantitatively precipitated by TCA (at a concentration of a few percent),

DUKE UNIVERSITY CENTRAL UNIVERSITY LIBRARY

which also concentrates them. The supernatant is discarded, which rids the sample of most low-molecular-weight impurities. The TCA precipitate should be redissolved in base for subsequent BCA assay.

Acid digestion–ninhydrin assay

The acid digestion/ninhydrin assay (see Basic Protocol 4; Rosen, 1957) takes considerably more time than other methods that depend on starting with protein samples in solution. This assay is useful for dried solid samples such as plant material because the whole sample is hydrolyzed under conditions that convert peptides and proteins to amino acids suitable for conventional chromatographic analysis (Marks et al., 1985). Nucleic acid bases such as adenine apparently do not interfere with the ninhydrin reaction, which can also be advantageous with complex samples.

UV spectrum analysis

The ultraviolet (UV) absorption spectrum for a sample protein can be used to quantitate the protein and to evaluate the purity of a sample. Figure 3.4.7 shows the UV absorption spectra for glycyl-L-tyrosine. The molar absorption coefficient ε as a function of wavelength λ is dependent on pH. The glycyl moiety has negligible effect on the spectra, so they are close in general shape to those of tyrosine side chains in proteins. Tryptophan side chains (indole groups) have similar spectra at acid pH. However, tryptophan absorption is considerably more intense at 275 to 280 nm, by a factor of nearly 4. Thus, although different proteins have very variable tyrosine-tryptophan compositions, the general shape of their UV absorption spectra in acid are fairly close to those of tyrosine at neutral and acid pH.

Proteins in neutral and acid solutions exhibit a deep trough in absorption at 245 to 250 nm Most proteins, except for heme proteins and proteins with cofactors such as NADH, do not absorb from either tyrosine or tryptophan above 300 to 310 nm. Increased absorption at ≤250 nm and/or ≥300 nm is a strong indication of the presence of compounds that interfere with A_{280} measurements and their interpretation. The effectiveness of techniques such as dialysis and size-exclusion chromatography for removing interfering UV-absorbing compounds can be monitored by analyzing the sample for absorption at 250 nm (trough), 280 nm (peak), and 300 to 310 nm (residual). Ratios of these absorbances are often used to determine whether the UV spectrum is that of pure or contaminated protein. For example, the peak/trough ratio (A_{280}/A_{250}) for proteins in neutral and acid solutions is almost always ≥2.

When a protein solution is shifted from acidic to alkaline pH, the absorption spectrum for tyrosine changes radically due to alkaline ionization of the tyrosine hydroxyl group. The maximum change in absorption occurs at 295 nm, with a $\Delta\varepsilon_{295}$ of 2470 M^{-1} cm^{-1}. Proteins absorb rather little at 295 nm, except for some contribution by tryptophan groups. However, titration of trytophan side chains does not produce a shift in A_{295}, so observation of changes in A_{295} with changing pH can be ascribed to tyrosine in the absence of interfering compounds that behave similarly to tyrosine. Analysis of UV absorption spectra, especially at 280 and 295 nm, for a purified protein under acid and alkaline conditions can be used to characterize the tyrosine and tryptophan content of the protein (Bencze and Schmid, 1957). With care, both tyrosine and tryptophan can be quantitated by the Bencze-Schmid method to within 3% to 4% of values obtained from complete analysis of amino acid content by hydrolysis and chromatography (Stein and Moore, 1954; Chang, 1992).

A number of sophisticated UV spectrum–based methods for protein quantitation and characterization use absorption at 205 nm and 224 to 236 nm (Bencze and Schmid, 1957), and second-derivative spectra of enzymatic digests of proteins (Bewley, 1982). See *UNIT 3.1* for additional information and discussion. It is necessary to remove oxygen from the spectrophotometer by nitrogen purging for measurements at very low wavelengths ("hard" UV, <220 nm).

All proteins absorb strongly at 205 nm, so at first glance this seems an attractive means for quantitating protein. However, most published methods describing hard UV absorbance are based on the behavior of pure, mostly single-subunit proteins. Buffers with carbonyl groups and many other impurities also become strongly absorbing in the hard UV range, and the problems of conventional UV absorbance are magnified in the hard UV range.

Coomassie dye binding assay (Bradford assay)

Coomassie blue dye (see Basic Protocol 6) produces a rather large absorption spectrum shift in the visible-light range when it binds to many globular proteins. The strong binding forces are partly, but not entirely, due to electrostatic attraction between dye molecule sulfonate groups (two on the G250 dye molecule)

BCU IASRI LIBRARY UNIVERSITY COPYRIGHT

and cationic groups of proteins when they are made quite acidic. The pH of the reaction mixture is low enough to thoroughly convert proteins to cations, but not so low that any sulfonate groups can become neutralized. The low pH of ~0.8 M phosphoric acid also causes most proteins to expand so that they become exposed to the triphenylmethane, organic, and nonpolar sectors of the dye to enhance binding (Craig, 1967). Proteins that do not bind anionic dye, even in very low pH, may not bind Coomassie dyes. Early research on Coomassie dye–based protein assays used globular proteins, which are known to avidly bind dye and other similar anions such as detergent anions (Edsall and Wyman, 1958). Albumin, hemoglobin, chymotrypsinogen, and cytochrome *c*, which Bradford used to calibrate the method (Bradford, 1976), are particularly able proteins in this regard. However, other classes of proteins are quite unlike these globular, organic anion–binding proteins and these differences may be at the root of some of the failures reported for the Bradford method (Pierce and Suelter, 1977). At any rate, the Bradford method is especially simple and has good sensitivity when it is calibrated with proteins to which it is sensitive (e.g., albumin).

Jernejc et al. (1986) compared four different methods for determining total protein—Kjeldahl nitrogen, biuret, Lowry, and Coomassie dye binding—for each of eight stages in the isolation of proteins from mycelia. They found that the Coomassie dye binding method often grossly underestimated protein content, by factors >2-fold, relative to the other methods tested. Although Coomassie dye binding is an easy and convenient assay, its reliability must be verified for each experimental system.

A similar method is the Udy dye binding method, which uses acid orange 12 dye, a sulfonated azobenzene dye. The techniques was originally developed for food proteins, and it apparently compares well with Kjeldahl nitrogen analytic criteria (Udy, 1956).

Critical Parameters

There are two endemic problems in total protein assays. First, there is the issue of interfering compounds and how to remove them or minimize their effects. Second is the intense barrage of advertisements for reagents for measurement of total protein; these promise simplicity, sensitivity, and by implication suggest there is little need to consider what interfering compounds may do, how they operate, or in what concentrations they operate. In crude proteins and at many stages in protein purification, interfering compounds often are present in concentrations one, two, or even three orders of magnitude larger than protein concentrations. Some of the well-advertised means for measuring total proteins are based on calibration with pure proteins such as crystalline bovine serum albumin, which can be expected to behave well. However, good performance in calibration with single, fairly pure proteins frequently does not translate into reliable performance with real samples—tangled mixtures of carbohydrates, lipids, and nucleic acids with proteins and glycoproteins. In some cases, when samples are crude, approximately half the effort needs to be devoted to controls and to simple steps that can be taken to either eliminate interference or at least help understand it. Support Protocols 2 and 3 describe two techniques—dialysis and TCA precipitation—for removing low-molecular-weight interfering compounds.

It should be noted that calibrating a total protein assay using a pure protein, usually bovine serum albumin, as a reference standard is common practice. However, that does not ensure that data from crude samples, taken through the same procedures, accurately quantitates total protein in crude samples.

Variability in BCA analysis

There are a number of factors that contribute to variability in the BCA assay: the temperature and duration of the incubation step just before spectrophotometry, the use of too much protein, the choice of calibration protein, and the presence of interfering compounds in samples of unknown character. It may be helpful to experiment with the temperature and duration of incubation. Sometimes incubating the sample 30 min at 60°C can accelerate color development without loss of color stability (Smith et al., 1985; Goldschmidt and Kimelberg, 1989). However, incubated samples must be cooled adequately before making spectrophotometric measurements, because residual temperature gradients in the cuvettes can cause refractive index gradations or striations, which distort the optical path producing anomalies and errors. These errors can be neutralized by remixing samples until their temperatures are close to the temperature of the cuvette and they appear uniform by simple visual inspection.

BCA calibration plots (see Fig. 3.4.3) show definite curvature downward for most proteins in excess of ~90 to 100 µg protein/ml final assay volume. Such nonlinearity can occur

UCSD ASHOKA TRAN UNIVERSITY LIBRARY

when the protein or polypeptide are present in excess with respect to the amount of reagents (Cu^{2+} and BCA) available to develop color.

There is considerable variation in the slope of calibration plots and therefore in apparent sensitivities, depending on the protein used as a calibration standard. For conventional proteins—e.g., BSA, chymotrypsin, and ribonuclease—slopes can vary by as much as a factor of two (Smith et al., 1985). If gelatin is used for calibration with an incubation of 30 min at 37°C, the variation can be up to 3-fold. Some preparations of proteins, even "crystalline" and lyophilized proteins, still contain appreciable amounts of water and/or salts used in isolation or crystallization. Water contents may be measured by the dry weight method (see Basic Protocol 7). Some freeze-dried preparations are actually only 95% protein or even less. Accordingly, water and other contaminants in supposedly dried proteins may contribute to lowered slopes, sensitivities, and apparent absorption coefficients.

UV absorption

UV absorption spectra are useful for quantitating and characterizing pure proteins (also see *UNIT 3.1*). However, UV absorption is probably the most profoundly and easily distorted analytic method of quantitating proteins because concentrations of UV-absorbing contaminants as low as 10^{-4} to 10^{-5} M can affect the spectra. Thus caution is necessary when analyzing protein samples that are not very pure. Pigments, oxidation products, tannin-like substances, Maillard and other condensation products—all manner of biochemical compounds and natural products—all absorb at ultraviolet wavelengths, sometimes strongly, potentially causing very large errors (at least an order of magnitude). If a protein sample absorbs UV above ~320 nm, it is likely that appreciable and perhaps unacceptably large amounts of interfering compounds are present. Elaborate means have been proposed by a number of authors for UV analysis of total protein (reviewed by Peterson, 1983); nearly all are built on the supposition that no UV-absorbing interfering compounds are present in the protein sample. In practice, this supposition is very shaky, particularly at early and intermediate stages in protein purification of proteins. It may be valid for rather well-purified proteins. In general, UV absorption should be used in conjunction with other methods for analysis of total protein to correlate results. Additionally, UV absorption spectra can be used in a reverse sense, in conjunction with other analyses, to estimate the amounts of absorbing impurities (Beyer, 1983).

TCA precipitation

Trichloroacetic acid precipitation may also be affected by reagents used to prepare the sample. Chang (1992) describes a procedure for TCA precipitation of a solution containing large amounts of the strong anionic detergent sodium dodecyl sulfate (SDS). Sometimes it is useful to precipitate the interfering compounds leaving the proteins in solution. Polyethyleneimines (PEI; Sigma) can be used to precipitate nucleic acids, which have a UV absorption peak at 260 nm (Jendrisak, 1987). PEI does not absorb in the ultraviolet range. However, neither TCA nor PEI is free of cross-precipitation, so it may be necessary to experiment with the concentration of precipitant, pH, and temperature to optimize a particular precipitation step.

Anticipated Results

Table 3.4.4 presents a summary of the detection ranges to expect for the assays described here.

Table 3.4.4 Summary of Assays for Quantitating Total Protein

Assay	Sample size	Detection range (μg/ml)
Biuret	1 ml	1000–10,000
Hartree-Lowry	1 ml	100–600
BCA	100 μl	200–1000
Ninhydrin	1 ml	20–50
UV absorption	1 ml	30–300
Coomassie dye binding	100 to 200 μl	60–300
Dry weight	0.5 to 10 ml	2000–10,000

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Time Considerations

Basic Protocols 1, 2, and 3 (biuret, Hartree-Lowry, and BCA assays) require one hour for measuring sample, mixing, incubation, and reading the absorbance. Basic Protocol 4 (acid digestion–ninhydrin detection) requires one hour on the first day to measure the sample and seal the tubes, followed by an overnight hydrolysis. On the second day, 1 to 2 hr are required for opening the tubes, neutralization, mixing reagents, heating, and reading the resulting color. Basic Protocol 5 (UV absorption) is the simplest of the methods described in this unit, taking only about 30 min to make dilutions, warm up the spectrophotometer, and measure the absorbance curve. Basic Protocol 6 (Coomassie dye binding) is also fast, requiring 20 to 30 min. Basic Protocol 7 (dry weight determination) requires a long drying time (4 hr to overnight) plus 10 to 20 min each time the container is weighed.

Kinetic Assay Methods

The design and use of a particular enzyme assay is dependent on the objectives of the particular investigation. If the focus is on enzyme purification or issues of clinical biochemistry, experimental protocols typically require optimizing conditions for all substrates and effectors—e.g., with respect to pH value, temperature, buffering agent, and ionic strength. However, optimal conditions may not be reasonable for all parameters and factors. For example, substrate instability may preclude studies at the enzyme's optimal pH or at the physiological temperature. Thus, Silverstein and Sulebele (1969) examined the exchange rates of malate dehydrogenase at 1°C to avoid problems arising from the decomposition of oxaloacetate. Likewise, in clinical studies and enzyme purification, saturating concentrations of substrate(s) are typically required, although this may not be possible or even desirable in many instances, as limitations in substrate solubility or substrate inhibition of the enzyme may discourage the use of elevated concentrations. The focus in clinical studies and enzyme purification is on providing good estimates of the activities of a specific enzyme in a number of physiological samples with a rapid, straightforward, and reproducible assay method. However, for the kineticist the objective is to characterize the initial rates of the enzyme-catalyzed reaction under a wide set of conditions. It is through these detailed studies, often carried out at subsaturating substrate concentrations, that the investigator is able to determine the true optimal parameters to be used in protein purification and clinical studies, as well as to probe the dynamics and mechanism of the reaction and its modulation by other factors. The purpose of this unit is to provide a brief review of issues important in the design of initial-rate assay methods.

In most instances, the investigator already has some information about the kinetic properties of the enzyme, obtained from preliminary experiments as well as from the literature. It is necessary to have an approximation of the magnitude of the Michaelis constants of all the substrates in order that detailed initial rate studies can be effectively designed. Certainly, information on the identity of the substrates and products is required, along with an effective procedure for monitoring substrate depletion or product accumulation. The nature of the reaction and the properties of the substrates help dictate the assay procedure used. Enzyme-assay methods include those based on spectrophotometry, radiometry, pH-stat, turbidometry, polarography, and fluorometry. Spectrophotometric and fluorometric assay protocols rely on the differences in spectral or fluorescent properties, respectively, of the product(s) relative to the substrate(s). With radiometric procedures, effective means for separating labeled substrate(s) from labeled product(s) must be available so that the amount of product formed at a given time can be accurately measured. Those reactions that utilize or generate protons (or hydrons) can be followed by pH-stat methods. If the reaction studied results in a change in solution turbidity (e.g., caused by aggregation of a macromolecular complex), then turbidometric protocols can effectively assay for the protein that causes the change in turbidity. All of these methods, as well as others, can be found in Bergmeyer (1983).

GENERAL ASPECTS OF ASSAY DESIGN

An enzyme's progress curve (i.e., a plot of product formation or substrate depletion as a function of time; see Fig. 3.5.1) consists of four phases that are of interest to the investigator. The duration of the **pre-steady-state** region is relatively short and is typically followed via rapid-flow or relaxation techniques. Discussion of this region of the progress curve is beyond the scope of this unit, but a review of these techniques has recently appeared (Fierke and Hammes, 1995). The next portion of the curve is the **steady-state** phase, a longer phase characterized by relatively constant concentrations of each of the individual enzyme forms (e.g., the enzyme-substrate binary complexes). During the third phase of the progress curve—the **post-steady-state** region—the levels of these enzyme complexes change rapidly, until the last phase—**equilibrium**—has been reached. Each of these phases contains information of use to the investigator. The steady-state portion of the curve typically exists for a few to several hundred seconds. It is this region of the curve that is most accessible to the majority of investigators. In addition, the relatively straightforward mathematical treatment of steady-state kinetics provides an excellent foundation for the subsequent characterization of the enzyme system. Because enzyme rate expressions can be quite complex, a number of

assumptions are made to linearize the equations. The investigator should ensure that each of these factors are addressed when any assay protocol is being designed.

Maintaining Constant Reaction Conditions

The status of each experimental parameter—e.g., temperature, ionic strength, and pH—should remain constant over the time course of the assay.

Temperature

Prior to initiation of the reaction by addition of a small aliquot of enzyme or substrate, the reaction mixture should be thermally equilibrated with an accurately controlled constant-temperature water bath for several minutes. If the substrate is thermally stable, this incubation should be for ≥10 min or until the desired reaction temperature is reached. If the substrate is unstable at this temperature, it may be necessary either to assay at a different temperature, to correct for substrate decay with time, or to initiate the reaction by addition of a small aliquot of substrate solution that was freshly prepared and maintained in an ice bath. When the reaction is initiated by addition of either the enzyme or the substrate, the volume of the aliquot should be small enough to minimize any alterations in temperature upon addition. Typically, there is at least a hundred-fold difference in volume between the reaction mixture and the initiating aliquot. If the enzyme and substrate are stable under the assay conditions, then both solutions should be preincubated at this temperature.

It should be emphasized that valid initial rate experiments are only obtained when good temperature control is maintained. The temperature-regulated water bath should have a variability of ≤0.1°C. When the reaction is initiated, the solution should be thoroughly mixed. If reaction progress is followed using an instrument such as a spectrophotometer, the sample compartment should be thermally isolated.

Another issue of concern is choice of the temperature at which enzyme activity will be measured. In 1964, the International Union of Biochemistry (IUB) recommended a temperature of 30°C. Clinical chemists have often suggested a change to 37°C. However, the final choice of temperature will be dependent on the system being investigated. For example, the activity of glutamate dehydrogenase isolated from the hyperthermophile *Pyrococcus furiosus* is negligible at both 30°C and 37°C; the enzyme exhibits maximal activity at 97°C (Klump et al., 1992). Clearly, at some point in the investigation, the effect of temperature on the catalytic activity will have to be characterized.

PCU IASL CENTRAL UNIVERSITY LIBRARY

Buffer selection

In setting up the assay protocol, care should also be exercised in selecting an appropriate buffer agent. Unfortunately, many investigators choose a buffer solely on the basis of the desired pH of the reaction medium. Many excellent buffers, however, have a significant oxidation-reduction potential that can severely alter an enzyme's activity. For example, cacodylate ($pK_a = 6.27$) and other organoarsenicals have a potent oxidizing potential under acidic conditions. Borate ($pK_a = 9.23$) and other borate-based buffers form complexes with many diols, polyols, carbohydrates, and ribonucleotides; for example, in the presence of borate ion, both L- and D-serine form a transition complex and strongly inhibit γ-glutamyl transpeptidase (Tate and Meister, 1978). Hence, care should be exercised in selecting a buffer.

In determining which buffer is optimal for a given enzyme system, it is best to examine the enzyme's activity with as many buffers as possible. Buffers in whose presence the enzyme exhibits high activity should then be examined to determine if the buffering agent interacts with the protein. If pH and ionic strength are held constant, the enzyme activity should be independent of the buffer concentration. Another factor of importance in selecting the appropriate buffer is the capacity of the buffering agent to bind metal ions. Ideally, a good buffer will not form any significant complexes with metal-ion cofactors.

Metal-ion concentrations

The role of metal ions is crucial with many enzymes, particularly with systems that require nucleotides—e.g., phosphotransferases. Care must be exercised in designing initial-rate assays to ensure that the concentration of free metal ions does not vary significantly with substrate concentration. Thus, when varying the concentrations of substrates such as ATP, the concentration of free, uncomplexed Mg^{2+} should remain relatively constant. One of two methods is commonly utilized to achieve this end: either (1) maintaining the total nucleotide concentration and the metal concentration at a constant stoichiometric ratio (e.g., 10:1) or (2) maintaining a constant excess of metal ion over the total nucleotide concentration (e.g., 1.0 mM free Mg^{2+}). The second method, which has been demonstrated to be the preferable of the two (O'Sullivan and Smithers, 1979), requires knowledge of the stability constant for the metal-ion–nucleotide complex under the conditions of the assay.

Substrate Stability and Purity

It is crucial to establish the degree of stability of the substrate as well as that of any enzyme effector under the assay conditions (also see discussion of Maintaining Constant Reaction Conditions). Substrate and effector stabilities can be tested by preparing a solution of the compound at a concentration that will be used experimentally with the other components of the assay mixture, but without the enzyme. Then, samples are removed at different periods of time, usually over a period of several hours, and assayed either chemically or enzymatically (Bergmeyer, 1983). A plot of concentration as a function of time will reveal if the substrate is stable or if there is a decay. When present, this decomposition is usually a first-order process and can be described by the equation $[S]_t = [S]_0 e^{-kt}$, where $[S]_t$ and $[S]_0$ are the substrate concentrations at time t and time 0, respectively, and k is the first-order rate constant. If the decomposition is greater than first-order or composed of more than one first-order process, then the decay must be evaluated by the appropriate expression, which can be found in any basic kinetics text.

An issue related to substrate stability is substrate purity. Impurities in the substrate, effectors, or enzyme preparation can be potential sources of experimental error. Because alternative substrates and competitive inhibitors are often structurally similar to the substrate and frequently have similar chemical and physical properties, it is not surprising to find these compounds as impurities in commercial substrate preparations. Spectral and chromatographic analyses, as well as enzymatic analysis, are crucial in establishing the purity of a particular biochemical substance. If impurities are present in a reaction mixture, a kinetic analysis will give wrong estimates of the kinetic parameters (Allison and Purich, 1979). Heavy-metal ions are often found as impurities in commercial substrates. To remove these, it may be necessary to recrystallize the substrates, possibly in the presence of a chelating agent such as EDTA.

These issues of purity and stability are also pertinent for any modulators of enzyme activity, including the product(s). The products have to be stable over the time course of the assay. In some instances, the precise nature of the true product of the enzyme-catalyzed reaction may not be known. In these cases, the investigator may follow the reaction via substrate depletion. It is frequently useful to do a kinetic analysis of freshly prepared substrate in the absence and

FOR INSTRUCTIONAL USE ONLY

presence of enzymatically prepared product. A decent understanding of the possible presence of product inhibition in initial-rate experiments is always useful to the protein chemist.

Enzyme Stability and Purity

Enzymes often undergo a slow inactivation. Usually, the rate of this inactivation is accelerated by dilution of the stock enzyme preparation. Efforts have to be made to eliminate or lessen the loss of enzyme activity with time. Often, multisubstrate enzymes are stabilized by the presence of a substrate. For example, tubulin:tyrosine ligase is stabilized by the presence of its protein substrate (Deans et al., 1992) and the presence of Mg^{2+}–ATP is known to stabilize a number of phosphotransferases. If the enzyme inactivation can be retarded by the presence of a substrate, the investigator should note the amount of that substrate that is present with the enzyme so that proper corrections can be made when the reaction is initiated with the full assay mixture.

Other agents—e.g., glycerol, certain salts, high-ionic-strength solutions, and EDTA—have also been used to stabilize proteins. Often, inactivation is a result of surface denaturation or adsorption of the enzyme on glass surfaces following dilution. The presence of stabilizing agents and/or use of plastic containers can lessen these effects significantly. The presence of serum albumin or another protein will frequently minimize the effects of enzyme dilution; the investigator should test several proteins when this technique is used. The stabilizing protein may also bind the substrates or the enzyme's cofactors; if this is the case, corrections have to be made.

If a stabilizing agent cannot be identified, the inactivation should be minimized by using the smallest dilution possible. If practical, the reaction may be initiated by the addition of one of the substrates. Corrections for loss of enzyme activity can also be made by establishing an activity-decay curve. However, it should be verified that the loss of activity is due to total inactivation and not simply to a conformational change to a form having less activity (i.e., a form with different kinetic parameters). This possibility could be tested by kinetic assays at significantly different times following dilution or by two reference assays, one using a saturating substrate level and the other using a subsaturating substrate level.

The presence of thiol reagents—e.g., 2-mercaptoethanol, dithiothreitol, or dithioerythritol—is routinely helpful in maintaining activity for those enzymes that require reduced thiol groups for activity. Care must be exercised that the reducing agent does not produce other effects. For example, γ-glutamylcysteine synthetase is inhibited by the presence of thiol reagents even though cysteine is a substrate (Seelig and Meister, 1985).

Enzyme purity is also an issue of concern. It is important in early initial-rate studies to eliminate contaminating activities and to demonstrate that any minor activity does not substantially affect the reaction being studied. For multisubstrate enzymes, this can be readily accomplished by observing the stability of each substrate, effector, and product separately in the presence of the enzyme preparation. Adenylate kinase is a common contaminant in preparations of a wide variety of phosphotransferases and other nucleotide-dependent enzymes. This contaminating enzyme can be inhibited by performing the assay at high ionic strength (Bowen and Kerwin, 1955). Addition of elevated levels of AMP will also inhibit adenylate kinase. However, many phosphotransferases are also inhibited by this mononucleotide or are themselves inhibited by high ionic strength. Purich and Fromm (1972) and Lienhard and Secemski (1973) have shown that the multisubstrate analogs P^1,P^4-di(adenosine-5′)-tetraphosphate and P^1,P^5-di(adenosine-5′)-pentaphosphate are potent and specific inhibitors of this activity.

In some instances it may be impossible to completely eliminate side reactions. Enzymes that have branched reaction pathways (i.e., multifunctional enzymes) will exhibit two pathways. Most multifunctional enzymes are transferases having multiple acceptor specificity. Glucose-6-phosphatase catalyzes not only the hydrolysis of glucose-6-phosphate but also its synthesis; thus, it may effect the transfer of phosphoryl groups from pyrophosphate, carbamoyl phosphate, or other glucose-6-phosphate molecules (Nordlie, 1982). This synthetic role of glucose-6-phosphatase is not a minor activity; at a concentration of 100 mM D-glucose, the synthesis and hydrolysis activities are approximately equal. The enzyme γ-glutamyl transpeptidase catalyzes the hydrolysis of a number of γ-glutamyl-containing molecules (including glutathione and glutathione disulfide) and also exhibits a transferase activity in which the glutamyl moeity is transferred to any of a number of amino acid acceptors, particularly cysteine, glutamine, and methionine (Allison, 1985). The hydrolase and transferase activities of γ-glutamyl transpeptidase

BCU IASE CENTRAL UNIVERSITY LIBRARY

are approximately equal in the presence of a pool of acceptor substrates at their physiological concentrations (Allison and Meister, 1981). Asparagine synthetase catalyzes the glutamine-dependent synthesis of L-asparagine and also exhibits a significant glutaminase activity (Boehlein et al., 1994). In all of these cases, it is possible to use inactivation studies to observe the parallel loss of both (or all) activities with time.

Enzyme Concentration

The duration of the steady-state phase of an enzyme-catalyzed reaction is dependent on a number of factors. Perhaps the most important of these is the relative concentration of the enzyme and substrate. The ratio of the initial substrate concentration to the total enzyme concentration should be ≥100:1. With lower values, the steady-state phase will be of very short duration. It should be pointed out that this relationship holds for enzyme effectors as well. Thus, when investigating the influences of an activator or competitive inhibitor on enzyme activity, the total enzyme concentration should be much less than the concentration of the effector. This may prove difficult if the effector has a very tight affinity with the enzyme. In these cases, the protocols outlined by Williams and Morrison (1979) will prove useful.

Initial Rate and Steady-State Condition

In an experiment, the investigator typically measures the rate of an enzyme-catalyzed reaction by calculating the slope of the progress curve. This procedure is only valid if the plot of product concentration as a function of time has been demonstrated to be linear within the time frame of the assay. However, this is not the only criterion that determines initial rate and steady-state kinetics. Linearity has been observed in many non-steady-state systems (Allison and Purich, 1979).

The general rule of thumb is that initial rate conditions prevail when the substrate concentration is still within 10% of its starting value. This value is clearly acceptable for reactions that are thermodynamically quite favorable and that do not exhibit any significant product inhibition. However, if the equilibrium constant for the reaction is not large, an estimate of the degree of substrate-to-product conversion should be made. With smaller equilibrium constants, the initial-rate assay protocol necessarily must be more sensitive. In addition, if the product has very tight affinity for the enzyme, product accumulation can lead to significant errors in initial-rate determinations even in those cases where the degree of conversion is low. A preliminary test to assess this possibility is to look at initial rates in the absence and presence of a known amount of product. Where product inhibition is a problem, product can be depleted if an auxiliary enzyme system for doing this is present. Nevertheless, product inhibition can be an important regulatory scheme for an enzyme. Any kinetic characterization of an enzyme should include accurate measurements of the dissociation constants for all products. Product-inhibition studies can also assist the investigator in establishing mechanistic details of the protein undergoing evaluation (Rudolph, 1979).

In addition to establishing that the progress curve is truly linear, demonstrating that the degree of substrate depletion in the initial time course of the assay is low, and assessing the degree of product inhibition that may be present, the investigator should also demonstrate in the early stages of the kinetic studies that the rates observed are linear with respect to the total enzyme concentration ($[E]_{total}$). If true steady-state conditions are present, a plot of initial rates versus $[E]_{total}$ (in which the enzyme concentration is varied above and below the final value to be used in the initial-rate assays) should be linear.

Substrate Concentration Ranges

A wide range of substrate concentrations should be tested in preliminary studies. Such trials will provide an estimate of the Michaelis constant (K_m) and an assessment of whether substrate inhibition occurs at elevated substrate levels. These tests will also detect the possible existence of cooperativity. Once an estimate of the Michaelis constant has been made, a more detailed kinetic study can be made, in which the substrate concentration is typically varied from ~0.2 to 5.0 times the value of the apparent constant. It should be emphasized that reasonable estimates of the K_m value can only be made when initial rates have been obtained from substrate concentrations both below and above the true K_m value. For a one-substrate enzyme-catalyzed reaction:

$$K_m = [A](V_{max} - v)/v$$

where [A] is the substrate concentration, V_{max} is the maximal velocity of the reaction, and v is the velocity of the reaction at the substrate concentration. A series of substrate concentrations with their respective initial rate velocities

POLYTECHNIC UNIVERSITY LIBRARY

will provide an estimate of the Michaelis constant. In a standard double-reciprocal plot, the horizontal intercept is numerically equal to $-1/K_m$. For multisubstrate enzymes (see below), estimates of the Michaelis constants will be obtained from slope and intercept replots of the initial rate data. In addition, appropriate statistical treatment of the raw data should be provided (Wilkinson, 1961; Cleland, 1979a) for both K_m and V_{max} values (or k_{cat} values, equal to $V_{max}/[E]_{total}$, if those are reported). Note that, regardless of whether V_{max} or k_{cat} values are reported, the total protein concentration, as well as the specific activity of the enzyme used, should be reported whenever possible.

With enzyme systems utilizing two substrates, the concentrations of both substrates must be varied as described above. Typically, three solutions are prepared. One solution contains one of the substrates at its highest level. A second solution contains the second substrate at its highest level. The third solution contains the buffer, all cofactors, metal ions, auxiliary enzymes, and any other effectors, but no substrates. This third solution is used to prepare serial dilutions of the other two stock solutions. Thus, a matrix of initial rate measurements on both substrates can be evaluated from a single experimental trial. Figure 3.5.2 illustrates a typical double-reciprocal plot for a two-substrate enzyme-catalyzed reaction (where the the two substrates are A and B). In this example, Michaelis constants for the two substrates can be obtained by constructing slope and/or intercept replots of the data. For example, plotting the slopes of the five lines as a function of the reciprocal of the concentration of B will yield a straight line with a horizontal intercept numerically equal to $-1/K_B$, where K_B is the Michaelis constant for B.

For enzymes that utilize three or more substrates, the protocol described above can become unwieldy. Two procedures have been described to address the design of kinetic studies for these proteins. In the first method (Frieden, 1959), one of the three substrates is held constant at a concentration above its respective Michaelis constant that is still subsaturating. The other two are then varied as described above. This same procedure is then followed with each of the remaining substrates. Thus, multisubstrate enzymes are reduced to pseudo-two-substrate systems. One distinct advantage of this procedure is that standard graphical presentations of the data thus produced (e.g., via double-reciprocal plots) are identical to that shown in Figure 3.5.2. However, the concentration value for the third substrate have to be provided. In the second procedure, the concentration of one substrate is varied while the other substrates are held at a

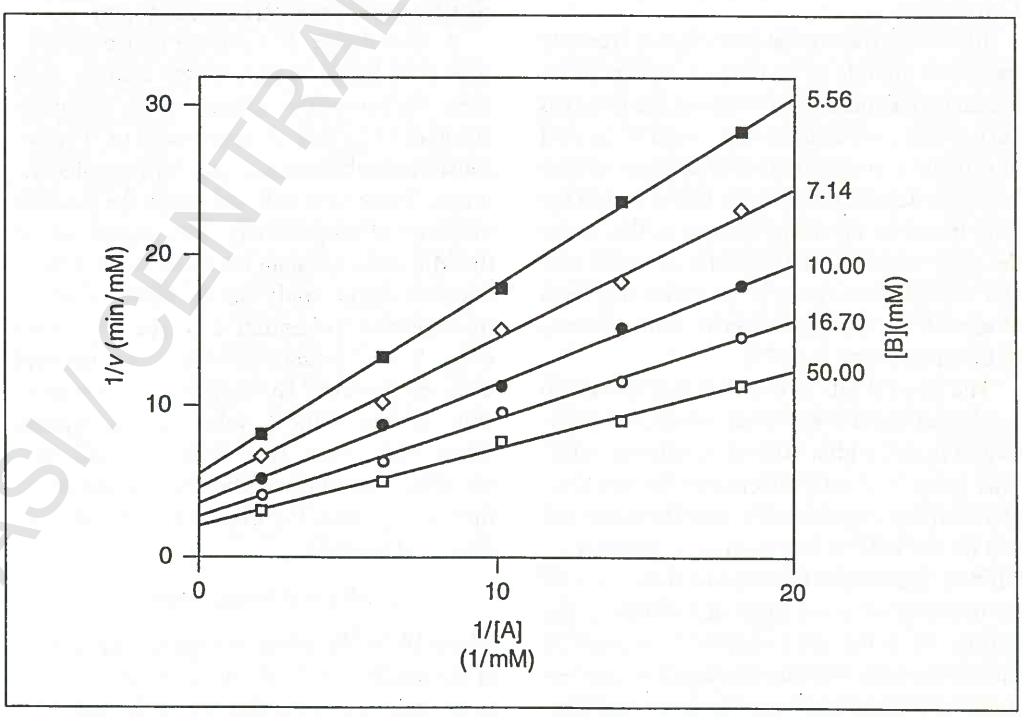

Figure 3.5.2 Double-reciprocal plot of a two-substrate enzyme-catalyzed reaction, where v = the velocity of the reaction and [A] and [B] represent the concentrations of substrates A and B respectively.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

constant ratio, although the absolute amounts are varied. This is then repeated for all remaining substrates until the concentration of each of the substrates has been varied (Fromm, 1967). One limitation with this approach is the difficulty in obtaining true Michaelis constants.

The presence of substrate inhibition can be an annoyance to an investigator who is attempting to determine the kinetic parameters of an enzyme as well as identify the binding pattern. However, the pattern of such inhibition can serve as a tool in understanding the kinetic and possibly the regulatory scheme for the enzyme. Substrate inhibition can occur as a result of a number of different causes—i.e., the formation of a dead-end complex with a particular enzyme form, the appearance of a different binding mechanism at elevated levels of substrate, the presence of an allosteric site for the substrate, or nonspecific inhibition that is due to an elevated ionic strength or another factor. When substrate inhibition occurs, in the case of multisubstrate enzymes, estimates of the K_i value (i.e., the dissociation constant for inhibition) for the substrate can be obtained from slope and intercept replots of the kinetic data. For enzymes having a single substrate, the data can be fit to an enzyme-rate expression containing a term for substrate inhibition ($v = V_{max}[S]/\{K_m + [S] + [S]^2/K_i\}$). In addition, estimates of K_m, K_i, and V_{max} can be obtained from double-reciprocal plots (Cleland, 1979b). Note that in such cases, double-reciprocal plots will be nonlinear, with the degree of curvature dependent on the magnitude of the K_i value. In these cases, it may be necessary to use a computer program to fit the data. Cleland (1979a) has provided a program to address substrate inhibition. In addition, one might consider utilizing a Marmasse plot (Marmasse, 1963). Although rarely used, this plot provides good estimates of K_m and K_i. A Marmasse plot is a plot of $1/v$ versus $(\alpha + 1/\alpha)$, where $\alpha = [A]/[A]_m$ and $[A]_m$ represents the concentration of substrate at which the velocity is highest (note that this is not V_{max}, as substrate inhibition is present.) This plot, when combined with the observation that $[A]_m = (K_m/K_i)^{1/2}$, will provide values for the kinetic parameters (Cleland, 1979b).

CONTINUOUS VERSUS STOP-TIME ASSAYS

As the best estimate for the initial rate of an enzyme-catalyzed reaction derives from the slope of the steady-state region of the progress curve, continuous assays are greatly preferable to single-point assays. If it is not possible to use a continuous assay, the investigator must demonstrate that the single-point assay is a true measure of the steady-state velocity of the reaction. In the single-point method, an aliquot of the reaction mixture is removed from the sample at a given time point after the reaction has been initiated (after a "blank" aliquot has been removed from the reaction mixture prior to the initiation step). Aliquots from at least four different time points are removed from the reaction solution; then the reaction is terminated and the amount of product formed (or substrate depleted) is determined. It should be ascertained that the termination procedure truly quenches the reaction. Once the steady-state relationship has been established, replicate kinetic analyses at each substrate concentration will provide sufficient data for a statistical analysis. The number of replicate samples that are assayed should also be reported.

COUPLED ENZYME ASSAYS

In many instances, continuous assays are made possible by the presence of auxiliary enzymes. Product formation is measured by having the product react further with another enzyme (or enzymes). Although such assay systems are convenient, precautions must be exercised to ensure that the initial rates observed reflect the enzyme that is undergoing investigation and not the auxiliary system. If the auxiliary system is influencing the initial-rate results, the reported values for the kinetic parameters will be in error and the double-reciprocals may exhibit considerable nonlinearity.

The product or products formed by the enzyme undergoing study clearly direct the choice of auxiliary enzyme(s). This coupling system should provide turnover in excess over that due to the enzyme being investigated. However, the degree of excess will vary depending upon the assay method, the nature of the coupling system, and the magnitude of the kinetic parameters for each auxiliary enzyme as measured under the same conditions being observed with the target enzyme. Once this information is in hand, the amount of auxiliary enzyme needed can be calculated (McClure, 1969; Storer and Cornish-Bowden, 1974). Test runs should then be undertaken using both the calculated and higher levels of auxiliary enzymes to insure that identical rates are obtained, indicating that a sufficient excess has been achieved. The auxiliary enzyme system should also have minimal effect on cofactors and effectors required by the target enzyme.

RUTGERS UNIVERSITY LIBRARY

Frequently, a small amount of product may be present in the reaction mixture as a contaminant. For example, commercial preparations of ATP often include a small amount of ADP. The contaminating product can be removed prior to initiation of the assay by incubating the reaction mixture with the auxiliary system. The system should also be checked to insure that no activity is observed in the absence of the auxiliary enzymes. Finally, care should be exercised when using commercial preparations for the auxiliary enzymes. Often these sources of proteins contain contaminating activities that may cause serious difficulties unless they are addressed.

BINDING STUDIES

Measurements of equilibrium ligand binding can frequently add to the characterization of an enzyme's binding mechanism, and also act as a tool in such procedures as molecular-receptor binding studies and radioimmunoassays. A wide variety of methods have been utilized in characterizing binding phenomena—e.g., gel filtration and equilibrium dialysis. The theory underlying this valuable tool can be found in any physical biochemistry text. Commonly, the binding data are analyzed with Scatchard plots (Scatchard, 1949) in which the number of moles of ligand bound per mole of total protein (ν) are plotted versus the ratio of ν to the free molar concentration of the ligand. These plots are frequently used to obtain values for the ligand dissociation constant, to identify interacting sites, and to estimate the binding capacity of the protein. Care should be exercised in this last use of the binding data, as it is easy to obtain a poor estimate of the stoichiometry of binding from Scatchard plots (Klotz, 1982, 1983). For example, a Scatchard plot of the binding of diazepam to benzodiazepine receptors is reported to provide an incorrect total number of receptor sites. Often, such problems are due to having only a few data points in the Scatchard plot at which the ligand concentration is above the half-maximum binding point. Just as in kinetic data, concentrations of the binding ligand both above and below this half-maximum point should be investigated (Klotz, 1982). Feldman (1983) has recently presented a statistical analysis associated with ligand binding data and Scatchard plots. As this paper points out, estimates of molar binding capacity should always be reported with the appropriate degree of statistical certainty. Without such statistical analyses, reports of the number of binding sites can be meaningless.

PRESENTATION OF INITIAL-RATE DATA

The description of the assay protocols used in connection with enzyme purifications, in clinical studies, and in all kinetic investigations should include a clear definition of the unit of enzyme activity. When possible, velocities should be expressed in terms of molarity changes with time, as molarity is an intensive variable. Other units, proportional to molarity, are in common use. In all cases, the conditions of the assay should be fully described, including the volume of the initiating aliquot, the specific activity, and the amount of enzyme used in each experiment. The international unit (U), defined as the conversion of 1 μmol of substrate to product per minute, is in common use. Another unit of catalytic activity, the katal, corresponding to the transformation of one mole of substrate per second, is also in use. It has been suggested that the latter unit be restricted to catalytic activities measured in a clinical context (Dybkaer, 1979).

Initial-rate data is frequently best presented via graphical displays. These visual linearizations of kinetic information provide a straightforward evaluation of the binding sequence and mechanism, as well as a ready appraisal of the kinetic parameters, reversible inhibition, cooperativity (both allosteric and hysteretic), and many other steady-state parameters. Whenever possible, slope and/or intercept replots should also be provided in the graphical display, perhaps as insets of the initial rate data. There are three methods frequently employed for depicting kinetic data, with the double-reciprocal plot (i.e., $1/v$ versus $1/[A]$; see Fig. 3.5.2) being the most common. The other common plots are $[A]/v$ versus $[A]$ and v versus $v/[A]$. Wilkinson (1961) has discussed each of these plots in terms of statistics. When the data are unweighted, the three graphical presentations are not statistically equivalent. However, this problem is considerably mitigated by proper analysis using computer methods and data weighting (Siano et al., 1975). As mentioned earlier, Cleland (1979a) has provided a number of computer programs for the analysis of data. Eisenthal and Cornish-Bowden (1974) have also introduced a novel method for graphical treatment of data that provides a useful tool for evaluating experimental error. An Eisenthal–Cornish-Bowden plot is based on the equation $(V_{max}/v) - (K_m/[A]) = 1$. Instead of a particular set of data (i.e., a single initial rate velocity with its respective substrate concentration) being represented by a point in a Car-

tesian coordinate system, the velocity (v) is denoted along the vertical axis and the substrate concentration ([A]) is denoted along the horizontal axis. The two points thus plotted are then connected by a line. Thus, whereas in the other graphical procedures the velocity and substrate-concentration data are represented by points, in the Eisenthal–Cornish-Bowden plot the same data are represented by lines. These lines, obtained from a set of initial-rate experiments, will intersect about a point equivalent to $v = V_{max}$ and $[A] = K_m$. Because median values of intersection points are used, outlier (i.e., aberrant) data will have minimal effects on estimates of the kinetic parameters. In addition, this plot is very useful in that calculations are not required and data do not have to be weighted. However, it does have limitations (Cornish-Bowden and Endrenyi, 1981, 1986). For example, the plot can become quite unwieldly with multisubstrate enzymes and in inhibition studies.

It has recently been suggested (Brand and Johnson, 1992; Johnson and Brand, 1994) that all of the graphical methods described above may be unnecessary now that personal computers and associated new methods of data analysis are available. For example, global analysis of biochemical data is a powerful tool that may prove to be quite useful in the analysis of enzyme kinetics (Beechem, 1992). However, these numerical methods have not yet been commonly applied to studies such as those of multisubstrate systems, equilibrium exchanges, or product inhibition. At this time, with proper statistical weighting of the data, multisubstrate systems are more readily appraised by one of the common graphical procedures. More importantly, these visual depictions of initial-rate data are a clear aid to any individual reviewing the kinetic experiments.

CONCLUDING REMARKS

Initial-rate assays are extremely useful tools in the detailed characterization of an enzyme. The behavior, mechanism, and regulatory properties of an enzyme can be readily assessed by straightforward assays. Such assays can frequently be completed within a day, once preliminary runs have identified the magnitude of the kinetic parameters and revealed those factors that affect activity. However, the details of the kinetic mechanism and regulatory properties of the enzyme can easily be obscured by poor assay design. The structural/functional role of an enzyme, as well as its regulation and control, can only be assessed by a reliable initial-rate assay. In addition, the data assembled from these rigorous studies permit the development of more reliable and sensitive assay protocols for protein purification and identification.

Biotinylation of Proteins in Solution and on Cell Surfaces

A protein is typically labeled with the water-soluble vitamin biotin to tag it for later recovery or for detection with biotin-binding proteins, such as avidin or streptavidin. Applications of this approach include identification and purification of cell surface–exposed proteins, measurement of ligand internalization kinetics, and temporal changes in protein distributions inside cells using light or electron microscopy. Many modified biotins, capable of reacting with protein lysyls, cysteinyls, or carbohydrates, are commercially available (see Table 3.6.1). It is usually possible to find at least one biotin reagent that can derivatize a given protein without affecting the function of interest. For instance, most enzyme activities are independent of protein modification on carbohydrate residues. Also, when used with enzyme-linked or radiolabeled avidin or streptavidin, biotinylation can be an effective technique for visualizing proteins that do not bind well to dyes after separation by SDS–polyacrylamide gel electrophoresis (SDS-PAGE; *UNIT 10.1*).

This unit contains three protocols for biotinylation of isolated proteins: attaching biotin to primary amines (e.g., ε-amino groups of lysyl residues; see Basic Protocol 1); attaching biotin to sulfhydryls (i.e., thiol groups of cysteinyl residues; see Basic Protocol 3); and attaching biotin to carbohydrate residues on proteins (see Basic Protocol 4). As biotinylation of lysyl and cysteinyl residues may alter protein function, modification of protein carbohydrates, which is usually innocuous, may be preferable if intact protein function is required (e.g., for activity assays or affinity purification). Biotinylation of cysteinyl thiols requires that disulfide bonds in isolated proteins be reduced before labeling (see Support Protocol 1).

Mild reaction conditions (e.g., in aqueous buffers at pH 7.5 to 8.5) and the small size of the biotin moiety also make biotinylation ideal for labeling surface proteins on living cells (see Basic Protocol 2). Such site-specific labeling enables investigators to monitor and/or effect subcellular purifications. Finally, this unit includes a brief description of methods for detecting biotinylated proteins (see Support Protocol 2).

COVALENT ATTACHMENT OF BIOTIN TO LYSINES

BASIC PROTOCOL 1

This protocol is a specialized version of the succinimidyl ester amidation reaction described in Basic Protocol 1 of *UNIT 15.2*. The reagent used, NHS-LC-biotin (see Fig. 3.6.1), has an *N*-hydroxysuccinimide (NHS) ester group to increase reactivity with primary amines and a long-chain (LC) spacer arm to extend the biotin from the protein surface, thus improving binding of subsequent reagents (e.g., avidin). The protein of interest is incubated with NHS-LC-biotin. Glycine is added to stop the reaction, and biotinylated proteins are purified by dialysis. This protocol works well over the range of 50 µl to 50 ml (and possibly for much larger volumes), so the volume of the reaction mixture should be chosen to suit the investigator's needs.

If biotinylation of lysines results in loss of protein function, biotinylation of thiols (see Basic Protocol 3) or carbohydrate groups (see Basic Protocol 4) may prove useful.

NOTE: NHS-biotin should be stored in the presence of desiccant at –20°C. When the reagent is thawed, it should be warmed thoroughly to room temperature before the container is opened.

Table 3.6.1 Commercially Available Biotinylating Reagents

Reagent	Supplier[a]	Molecular weight	Comments
Specific for reaction with primary amines (see Basic Protocols 1 and 2, Support Protocol 2)			
NHS-biotin	Pierce, Sigma, Vector Labs	341.4	Soluble in DMF or DMSO; store all NHS reagents at –20°C in presence of desiccant
Sulfo-NHS-biotin	Pierce, Sigma, Vector Labs	443.4	Water soluble
NHS-LC-biotin	Pierce, Sigma, Vector Labs	454.5	Soluble in DMF or DMSO; spacer arm improves accessibility of protein-bound biotin to affinity matrices
NHS-SS-biotin	Pierce	606.7	Soluble in DMF; cleavable by disulfide reduction
2-Iminobiotin-NHS	Calbiochem, Pierce	421.3	Soluble in DMF; exhibits pH-sensitive binding to avidin
Specific for reaction with sulfhydryls (see Basic Protocol 3, Support Protocols 1 and 2)			
Iodoacetyl-LC-biotin	Pierce	510.4	Soluble in DMF or DMSO; reacts with amino groups above pH 7.5
Biotin-LC maleimide	Sigma	479.6	Soluble in DMF; reacts with amino groups above pH 7.5
Maleimido-propionyl biocytin	Molecular Probes, Pierce	523.6	Soluble in DMF; reacts with amino groups above pH 7.5
Biotin-HPDP	Pierce	539.8	Soluble in DMSO; cleavable by disulfide reduction, regenerating initial cysteinyl
Specific for reaction with (oxidized) carbohydrates (see Basic Protocol 4, Support Protocol 2)			
Biotin-LC-hydrazide	Calbiochem, Pierce, Vector Labs	258.3	Soluble in water (to ~5 mM) and DMSO (to ~50 mM)
Biotin-hydrazide	Molecular Probes, Pierce, Sigma	371.5	Soluble in water (to ~5 mM) and DMSO (to ~50 mM)

[a]See *SUPPLIERS APPENDIX* for addresses and phone numbers of manufacturers.

Materials

~1 mg/ml purified protein
Coupling buffer (see recipe), ice cold
2 mg/ml NHS-LC-biotin (Pierce, Vector Labs) in *N,N*-dimethylformamide (DMF), room temperature, prepared just before use
50 mM glycine in coupling buffer
0.22-µm filter: e.g., Spin-X centrifuge filter (Costar) or syringe filter (Nalgene)
Additional reagents and equipment for dialysis (*UNIT 4.4* and *APPENDIX 3B*)

1. If necessary, dialyze the purified protein into coupling buffer to remove traces of interfering buffer components that may have been introduced during purification.

Complete exchange of buffer components can be assumed after a 48-hr dialysis against 100 vol of coupling buffer with three to four buffer changes. However, if the initial concentration of the interfering agent is relatively low, a 16- to 24-hr dialysis with two buffer changes is generally sufficient.

Azide, glycine, ammonium ions, and Tris are common buffer components that interfere with the biotin labeling reaction. Although these reagents should be avoided, reagents without primary or secondary amino groups can be included to stabilize the protein or to prevent labeling at functional sites. For instance, NaCl, $CaCl_2$, sucrose, glycerol, Triton X-100, and HEPES all can be used in the coupling buffer, if required.

CSU IAS / GENERAL UNIVERSITY LIBRARY

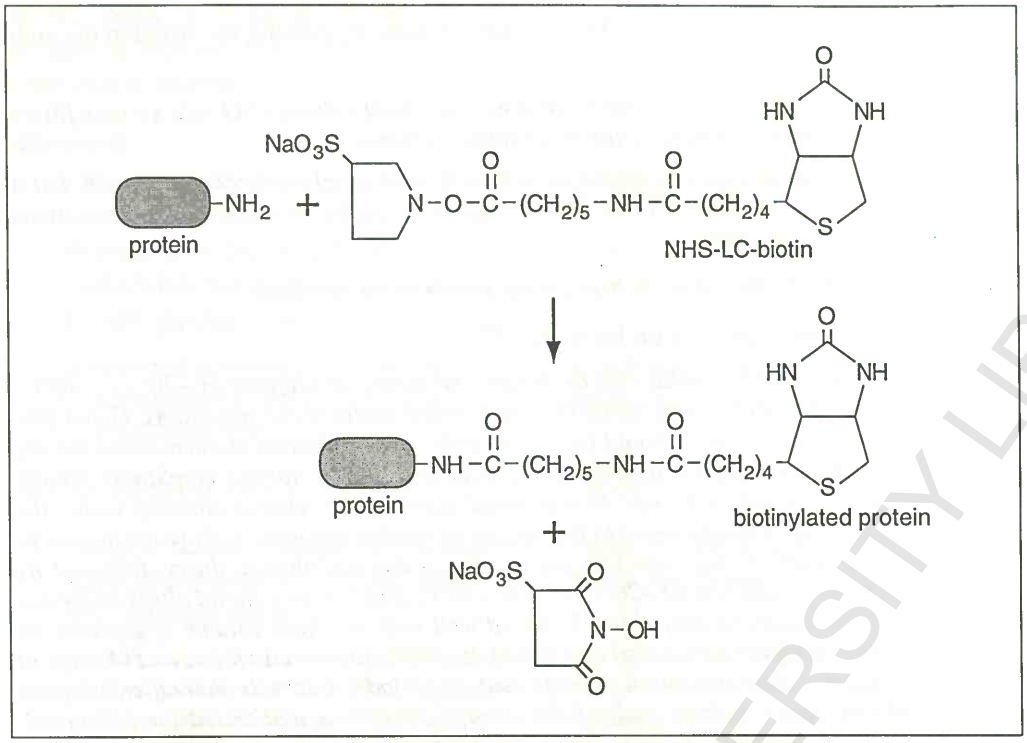

Figure 3.6.1 Reaction of *N*-hydroxysuccinimide (NHS)-LC-biotin with protein.

2. Rapidly add the freshly prepared suspension of NHS-LC-biotin in DMF to the protein in coupling buffer, using 1 vol biotin in DMF to 20 vol protein solution.

   The biotin/protein mixture may become turbid because NHS-LC-biotin forms a fine suspension in water, rather than a true solution. If the protein is sensitive to organic solvents or if the highest affinity binding to avidin afforded by the LC spacer is not necessary, sulfo-NHS-biotin (Pierce, Sigma, or Vector Labs) can be substituted for NHS-LC-biotin. Sulfo-NHS-biotin is very water soluble and can be added at the same final biotin/protein molar ratio (~10:1) from a freshly prepared aqueous stock solution without precipitate formation.

3. Incubate ~1 hr on ice. Mix occasionally.

   Optimal extents of biotinylation must be determined empirically for each protein and are a compromise between high levels of incorporated biotin and retention of protein function. The biotin/protein ratio during labeling and the length of labeling time recommended here have worked well for a number of proteins. However, biotin-to-protein ratios as low as 1:1 and as high as 60:1 have been reported. Similarly, optimal labeling times may vary between 1 and 18 hr.

4. Add 1 vol of 50 mM glycine to bind unreacted biotin.

5. Remove glycine and free biotin by exhaustive dialysis against coupling buffer, or another buffer of choice. Dialysis for ≥36 hr against three or more changes of 500 vol each is recommended.

   Once the labeling step is complete, any buffer, including Tris·HCl, can be used for dialysis (UNIT 4.4 & APPENDIX 3B). Unincorporated sulfo-NHS-biotin can be removed quickly by gel-filtration on an Econo-Pac 10DG desalting column (Bio-Rad) or a Sephadex G-25 column (Pharmacia Biotech; see UNIT 8.3). However, because any suspended micelles of unreacted NHS-LC-biotin will coelute in the void volume with the protein, proteins labeled with NHS-LC-biotin should be dialyzed overnight against one change of buffer before gel filtration.

BOULDER LIBRARY UNIVERSITY

6. For long-term storage, sterilize biotinylated proteins by passing the solution through a 0.22-µm filter.

   Spin-X centrifuge filters (Costar) work well for small volumes (<1 ml); syringe filters (Nalgene) are recommended for much larger volumes.

   Sodium azide also may be added up to 0.02% (w/v) to inhibit bacterial growth, but it is most effective below pH 7.0. Thimerosal (0.1% [w/v]) is more useful in solutions with higher pH values.

   CAUTION: *Sodium azide is toxic; wear gloves when handling.*

7. Store biotinylated proteins on ice or at 4°C.

   Some biotinylated proteins can be frozen and stored in aliquots at –20° or –70°C; others are reported to aggregate or lose function under these conditions. Generally, the biotinylated protein should be stored under the conditions recommended for the unlabeled protein. If no information is available about storage conditions for the protein of interest, it is wise to test small aliquots for relative stability under the following sets of conditions: (1) fast frozen in sterile cryogenic vials (Corning) or in test tubes with O-ring caps (Sarstedt) using a dry ice/ethanol slurry, followed by storage of aliquots (1a) at –20°C, (1b) at –70°C, and (1c) in a liquid nitrogen Dewar flask. Other aliquots should be (2) mixed well with an equal volume of glycerol (to make a 50% glycerol solution) and stored at –20°C, (3) stored on ice, and (4) kept at 4°C. Shortly after the initial storage and at periodic intervals thereafter, aliquots should be removed from each of the storage conditions and tested for biological, binding, or enzymatic activity. Once the most efficient storage condition has been determined, future preparations of the biotinylated protein should be stored accordingly in aliquots sufficient for one, or a few, experiments. Repeated cycles of freezing and thawing should be avoided.

   CAUTION: *Tubes stored under liquid nitrogen can explode on warming if liquid nitrogen has gotten inside the tube. Loosen caps on tubes immediately after taking them out of a liquid nitrogen Dewar flask.*

   The concentration of the biotinylated protein can be determined using any of the assays described in UNIT 3.4, and the concentration of protein-associated biotin can be measured in a variety of solid-phase competition assays with labeled avidin and known amounts of free biotin (Savage et al., 1992). However, because most assays with biotinylated protein are either qualitative or comparative, many investigators merely verify that biotinylation has occurred, i.e., by analysis of electrotransferred protein after SDS-PAGE (UNIT 10.10).

BASIC PROTOCOL 2

SIDE-SPECIFIC BIOTINYLATION OF PROTEINS ON CELL SURFACES

Biotinylation of proteins at the extracellular surface of living cells is a fast, nonradioactive means of labeling and tracking the plasma membrane during cell fractionation (Ingalls et al., 1986; UNIT 4.2). The biotinylated proteins also are easily isolated after membrane solubilization and affinity chromatography on columns containing bound avidin or streptavidin (Chia and Luna, 1989).

Biotinylation of living cells requires the water-soluble biotin derivative sulfo-NHS-biotin. The starting material is intact cells, either freshly isolated or from suspension or adherent cell cultures; control experiments starting with lysed cells or isolated membranes are, however, recommended to verify that cell integrity is maintained during the procedure. Cells are reacted with freshly dissolved sulfo-*N*-hydroxysuccinimide (NHS)-biotin for 30 min with mixing. Glycine is added to bind unreacted biotin, and cells are washed and lysed to prepare plasma membranes or solubilized proteins.

SCU IAS CENTRAL UNIVERSITY LIBRARY

NOTE: NHS-biotin should be stored in the presence of desiccant at –20°C. When the reagent is thawed, it should be warmed thoroughly to room temperature before the container is opened.

Materials

10^7 to 10^{10} cells of interest, in suspension (e.g., erythrocytes, leukocytes, or HeLa cells), or cultures of adherent cells
Physiological buffer, pH 7.4 (see recipe), ice cold
Sulfo-NHS-biotin (Pierce or Vector Labs)
10 mM glycine in physiological buffer

Additional reagents and equipment for lysing cells and isolating plasma membranes (*UNIT 4.2* and *UNIT 4.3*) or for solubilizing proteins for SDS gel electrophoresis (*UNIT 10.1*)

NOTE: Carry out all steps in this protocol at 4°C or on ice.

1. Remove serum proteins by washing the cells of interest at least three times with ice-cold physiological buffer, centrifuging cells in suspension for 5 min at ~500 × *g*, 4°C, between washes.

   Adherent cells are most easily washed and labeled while still attached to tissue culture flasks. To avoid labeling cytoplasmic proteins, the biotinylating agent should be thoroughly blocked and removed before dissociating attached cells from the flask (i.e., detach the cells after step 5). The buffer can be varied, depending on the preferences of the cells and the investigator. Dulbecco's PBS or Earle's balanced salts (e.g., Sigma) also work well. In contrast, PBS containing only ~5 mM phosphate (APPENDIX 2E) may not have sufficient buffering capacity. As in Basic Protocol 1, the principal consideration is to omit reagents containing primary amino groups that could compete for binding to the sulfo-NHS-biotin.

2. During the final cell wash, dissolve the sulfo-NHS-biotin in 0.1 vol ice-cold physiological buffer for a final concentration of 2 mg/ml (~5 mM). For instance, for ~10^{10} cells in a volume of 9 ml, dissolve 20 mg sulfo-NHS-biotin in 1 ml physiological buffer.

   If labeling attached cells, mix the sulfo-NHS-biotin with the entire amount of buffer immediately before adding the mixture to the cells. Minimize the amount of hydrolysis of the succinimide ester by limiting its exposure to water in the absence of cells.

3. Gently suspend the cells by adding ice-cold physiological buffer first. Then add 1/10 vol of dissolved sulfo-NHS-biotin. Mix gently without lysing the cells.

   Although labeling of cell-surface lysines proceeds faster as the pH of the buffer is raised from pH 7.4 to 9.0, so does the hydrolysis of the sulfo-NHS-biotin. In addition, many cells are lysed in higher-pH buffers.

4. Incubate 30 min at 4°C with gentle rotation or swirling.

   This procedure should label only surface-exposed proteins. Higher temperatures will result in increased biotinylation of membrane proteins, but much of the increase may be due to endocytic membrane turnover.

5. Block unreacted biotinylating reagent for ≥10 min by adding an equal volume of 10 mM glycine in physiological buffer. Wash cells with buffer three times as in step 1. Monitor the cells for lysis during centrifugation, using phase-contrast or differential interference contrast (DIC) light microscopy.

   If the cells are too fragile to withstand repeated washes, incubate with the glycine at 4°C for 15 to 30 min, then wash only one or two times. Blocking is faster at elevated pH, but pH 7.4 is adequate as long as the cells are not permeabilized during the washes.

BOSTON UNIVERSITY LIBRARY

6. Lyse the cells and isolate plasma membranes (see *UNIT 4.2*) or solubilize proteins for SDS-PAGE (see *UNIT 10.1*, Basic Protocol 1). Store biotinylated membranes in aliquots at –20°C.

It is usually a good idea to perform a parallel, control experiment in which cells are biotinylated after lysis or in which isolated membranes are biotinylated. The control procedure should label both surface-exposed and intracellular polypeptides, providing evidence for cellular integrity during the initial labeling procedure. The control can also demonstrate that if a protein of particular interest remains unlabeled under surface-labeling conditions but is labeled in isolated membranes or lysates, it is inherently capable of reacting with the sulfo-NHS-biotin reagent and, thus, is either a cytosolic protein or a membrane protein without accessible external lysines.

BASIC PROTOCOL 3

COVALENT ATTACHMENT OF BIOTIN TO THIOLS

An alternative to biotinylating lysyl groups (see Basic Protocol 1) is biotinylation of thiols or carbohydrate groups (see Basic Protocol 4). Several modified biotins react specifically with sulfhydryls (see Table 3.6.1). This protocol is described for iodoacetyl-LC-biotin in *N,N*-dimethylformamide (DMF). However, guidelines for using biotin-maleimide and *N*-(6-[biotinamido]hexyl)-3′-(2′-pyridyldithio)propionamide (biotin-HPDP) reagents are given in step annotations. Purified protein or membrane fractions are first subjected to disulfide reduction (see Support Protocol 1). The reduced material is mixed with iodoacetyl-LC-biotin. Unreacted components are then separated from labeled proteins by gel filtration or dialysis before the proteins are filter sterilized and stored.

Materials

0.5 mg/ml protein or cell fraction of interest, e.g., purified membranes
100 mM sodium phosphate/5 mM EDTA, pH 8.3 (*APPENDIX 2E*)
4 mM iodoacetyl-LC-biotin (Pierce) in DMF, freshly prepared or thawed from storage at –20°C

Additional reagents and equipment for reducing protein disulfides (see Support Protocol 1), dialysis (*UNIT 4.4* and *APPENDIX 3B*), gel-filtration chromatography (*UNIT 8.3*), or centrifugal filtration (*UNIT 15.1*, Support Protocol 3)

1. If necessary, reduce protein disulfides in the protein or cell fraction of interest (see Support Protocol 1) and remove the thiol-reducing agent by dialysis (*UNIT 4.4* and *APPENDIX 3B*), gel-filtration chromatography (*UNIT 8.3*), or centrifugal filtration (*UNIT 15.1*). Use the sodium phosphate/EDTA buffer to make up the solution of reduced protein.

If samples must be dialyzed for prolonged periods, nitrogen gas should be bubbled through the dialysis buffer to help exclude the atmospheric oxygen that will slowly (1 to 7 days) oxidize the reduced disulfides. EDTA chelates free metal ions that can catalyze this oxidation.

2. Add 20 µl of 4 mM iodoacetyl-LC-biotin in DMF for each milliliter of protein or cell fraction in the sodium phosphate/EDTA buffer.

For proteins with an "average" number of cysteines, i.e., 1.7 mol % (Table A.1A.1), this provides an equimolar ratio of iodoacetyl-LC-biotin. The cost and relative insolubility of biotinylated alkylating reagents contraindicate their use in a 5- to 10-fold molar excess over total thiols, as described in Basic Protocol 1.

Depending on the protein and activity to be studied, another thiol-directed biotinylating reagent may be preferable. At pH 8.3, iodoacetyl-LC-biotin reacts irreversibly and specifically with free sulfhydryls. Maleimide reagents (biotin-LC-maleimide and maleimidopropionyl biocytin) also irreversibly derivatize sulfhydryls but will react with some primary amines unless the pH is lowered to between 6.5 and 7.5. Biotin-

CUHK LIBRARIES

HPDP reacts rapidly and specifically through disulfide exchange with free protein sulfhydryls; consequently, proteins derivatized with biotin-HPDP should not be exposed to reduced thiol agents unless reversal of the labeling procedure is desired.

3. Incubate ~2 hr at room temperature or overnight at 0° to 4°C.

4. Remove unreacted reagent by gel-filtration chromatography (*UNIT 8.3*) or dialysis (*UNIT 4.4* and *APPENDIX 3B*).

5. Filter the solution through an 0.22-µm filter and store biotinylated proteins at 0° to 4°C or biotinylated membranes in aliquots at –20°C.

REDUCTION OF DISULFIDE BONDS

SUPPORT PROTOCOL 1

Reducing disulfide bonds may be necessary to create the free sulfhydryls on protein cysteines needed for biotinylation with thiol-directed biotin reagents (see Basic Protocol 3). Disulfide reduction can also be used to elute proteins tagged with the amine-directed reagent *N*-hydroxysuccinimide (NHS)-SS-biotin (see Basic Protocol 1) from avidin affinity columns. This protocol gives an effective method for reducing a thiol-sensitive disulfide bond that is not essential for the quaternary structure, e.g., that in immunoglobulins. The protein of interest is dialyzed into reducing buffer and mixed with reducing agent at elevated temperature (i.e., 37°C). Excess reductant is removed by gel-filtration chromatography (*UNIT 8.3*). The reduced protein is then ready for immediate biotinylation. In general, disulfide reduction can be assumed to be innocuous, if not advantageous, for proteins that reside in the cell cytoplasm, but it may perturb function in extracellular proteins or in the extracellular domains of transmembrane proteins.

Materials

1 to 10 mg/ml purified protein
Reducing buffer: 100 mM sodium phosphate/5 mM EDTA, pH 6.0 (*APPENDIX 2*)
Reducing agent: 50 mM dithiothreitol (DTT),100 mM 2-mercaptoethanol (2-ME), *or* 100 mM mercaptoethylamine·HCl (Sigma)
Econo-Pac 10DG desalting column (Bio-Rad) or Sephadex G-25 column (Pharmacia Biotech)
Additional reagents and equipment for dialysis (*UNIT 4.4* and *APPENDIX 3B*) and gel-filtration chromatography (*UNIT 8.3*)

1. If necessary, dialyze purified protein of interest into reducing buffer.

2. Add 1 vol of 1 to 10 mg/ml purified protein in reducing buffer to an equal volume of reducing agent. Incubate 1 hr at 37°C with occasional mixing.

   Each mole of DTT contains two thiols, so only half the concentration (50 mM) is required for the same concentration of reducing equivalents used for other reducing agents (100 mM 2-ME or 100 mM mercaptoethanolamine·HCl).

3. During the incubation in step 2, equilibrate an Econo-Pac 10DG desalting column or a Sephadex G-25 column with reducing buffer.

   The column should contain ≥10 vol of gel-filtration matrix (i.e., at least five times more volume than that of the reaction in step 2).

4. Cool the reaction to room temperature. Remove excess reducing agent by gel-filtration chromatography (*UNIT 8.3*) using the equilibrated column. Collect at least ten fractions, each containing ~1 vol (i.e., the same volume as the initial volume of protein solution).

   Alternatively, excess reducing agent may be removed by centrifugal filtration (UNIT 15.1, Support Protocol 3) or dialysis (UNIT 4.4 and APPENDIX 3B). If prolonged dialysis is

BOSTON CENTRAL UNIVERSITY LIBRARY

required, reoxidation of protein disulfides can be slowed by including 5 mM EDTA and/or by bubbling nitrogen gas through the dialysis buffer.

5. Read the absorbance of each fraction at 280 nm (A_{280}). Pool fractions that correspond to the first peak of absorbance.

6. As soon as possible after removing excess reducing agent, use the pooled fractions in cysteinyl-directed biotinylations (see Basic Protocol 3).

BASIC PROTOCOL 4

COVALENT ATTACHMENT OF BIOTIN TO CARBOHYDRATES

Biotinylation of protein carbohydrates requires oxidation of vicinal carbohydrate hydroxyl groups to aldehydes that can bind biotin-LC-hydrazide. Sodium *m*-periodate is used as the oxidizing agent for glycoproteins in solution, but enzyme-mediated oxidations can be used to oxidize glycoproteins of cells or membrane fractions. Briefly, glycoproteins are oxidized, excess oxidizing agent is removed by gel-filtration, biotin reagent is added, and the biotinylated glycoprotein is purified in a microconcentrator.

Materials

0.1 to 0.2 mg/ml glycoprotein
Labeling buffer: 100 mM sodium acetate, pH 5.5 (*APPENDIX 2E*)
30 mM and 3 mM sodium *m*-periodate (Sigma, mol. wt. 213.9) in water, freshly prepared and stored in the dark
5 mM biotin-LC-hydrazide (Calbiochem, Pierce, or Vector Labs) in labeling buffer (store ≤2 months at 4°C)
Stop solution: 100 mM Tris·Cl, pH 7.5 (*APPENDIX 2E*)
Econo-Pac 10DG desalting column (Bio-Rad) or Sephadex G-25 column (Pharmacia Biotech)
Microconcentrator
Additional reagents and equipment for dialysis (*UNIT 4.4* and *APPENDIX 3B*) and gel-filtration chromatography (*UNIT 8.3*)

1. If needed, dialyze the glycoprotein into labeling buffer.

2. Add 1 vol of 30 mM or 3 mM sodium *m*-periodate to 2 vol of 0.1 to 0.2 mg/ml glycoprotein in labeling buffer for a final periodate concentration of either 10 mM or 1 mM. Incubate ~30 min at room temperature in the dark.

   Because proteins differ in sensitivity to periodate, it is a good idea to try at least two different concentrations of the oxidant. For antibodies, O'Shannessy et al. (1984) report excellent results with 10 mM sodium m-periodate. For labeling a transmembrane glycoprotein that requires a detergent for solubilization, avoid the use of octylglucoside, which also reacts with periodate.

   Cell-surface carbohydrates on erythrocytes and on purified erythrocyte membranes have been biotinylated by labeling cells or purified membranes for 2 hr at room temperature with a solution containing 0.03 U/ml Vibrio cholerae neuraminidase (Boehringer Mannheim), 3 U/ml Dactylium dendroides galactose oxidase, and 0.4 mM biotin-LC-hydrazide in physiological buffer (Bayer et al., 1988). With many cells and cell membranes, however, those conditions will promote cell lysis and/or proteolysis.

3. During the incubation period (step 2), equilibrate an Econo-Pac 10DG desalting column or Sephadex G-25 column with labeling buffer.

   The column should contain ≥15 vol of gel-filtration matrix (i.e., at least five times more volume than that of the reaction in step 2).

PCU IASI CENTRAL UNIVERSITY LIBRARY

4. Remove unincorporated sodium *m*-periodate by gel-filtration chromatography (*UNIT 8.3*) using the equilibrated column. Collect at least ten fractions, each containing ~1 vol (i.e., the same volume as the initial volume of sodium *m*-periodate).

5. Read the absorbance of each fraction at 280 nm (A_{280}). Pool fractions that correspond to the first peak of absorbance.

6. Add 1 vol of 5 mM biotin-LC-hydrazide in labeling buffer. Incubate 1 hr at room temperature with occasional mixing.

   The amount of dilution of protein on the gel-filtration column can vary without significantly affecting the efficiency of the reaction.

7. Terminate the reaction by adding 5 vol stop solution.

   Tris, glycine, ammonium ions, and other buffer components containing primary amines should be avoided during the oxidation and labeling steps because they form reversible Schiff bonds with the carbohydrate aldehydes. These Schiff bonds will inhibit hydrazone bond formation. Primary amines are, however, good for stopping the labeling reaction. If the biotinylated protein is expected to be less than ~0.5 mg/ml after concentration, a carrier protein, such as BSA, can be added after the stop solution. Carrier protein helps to eliminate protein loss during concentration but will complicate quantification of the percent recovery of the biotinylated glycoprotein and of the number of biotins incorporated per glycoprotein molecule.

8. Remove unreacted biotin-LC-hydrazide by centrifugation in a microconcentrator with a molecular weight cutoff (MWCO) that is less than half that of the molecular weight of the protein in solution (*UNIT 4.4*). After concentrating the protein, suspend the sample to the initial volume with labeling buffer and reconcentrate. Repeat until the buffer has been changed a total of three times and the glycoprotein has reached the desired concentration.

   Any buffer in which the glycoprotein is stable can be substituted for labeling buffer at this step. To estimate the final glycoprotein concentration, assume no more than 50% loss during the entire procedure, as long as the protein is known to be well-behaved in solution. If precision is necessary, the molar ratio of biotin to glycoprotein can be calculated after determining protein concentrations (UNIT 3.4) and biotin concentrations (e.g., by solid-phase binding assays with avidin; Savage et al., 1992), after taking into account any added carrier protein. However, the estimate of 50% loss during experimental manipulation generally provides a reasonable starting point for most qualitative experiments (and is seldom off by more than a factor of 2).

9. Store the concentrated glycoprotein in aliquots at –70° or –20°C.

   For discussion of storage conditions, see Basic Protocol 1 (step 7 annotation).

BCU IASI / CENTRAL UNIVERSITY LIBRARY

DETECTION OF BIOTINYLATED PROTEINS

Once proteins or cells are biotinylated (see Basic Protocols 1 to 4), the next step is often detection (e.g., in the course of performing fluorescence or electron microscopy, assaying enzyme activity, or sizing proteins). Experimental samples and biotinylated standards can be analyzed simultaneously. This protocol gives brief instructions for separating proteins and visualizing them with ^{125}I-labeled avidin or avidin-based chromophores. Avidin-biotin complex (ABC) detection kits are available for isolated proteins (described in this protocol) as well as for proteins on fixed tissue, tissue sections, and microplate wells.

Materials

Biotinylated experimental protein (see Basic Protocols 1 to 4)
Biotinylated protein molecular weight standards (Bio-Rad or Vector Labs)
3% (w/v) BSA in PBS (*APPENDIX 2E*)
Nitrocellulose membrane
0.5 µCi ^{125}I-Bolton-Hunter-labeled avidin (DuPont NEN) in 5 ml avidin buffer (see recipe) *or* Vectastain ABC kit (Vector Labs) *or* ImmunoPure ABC kit (Pierce)

Additional reagents and equipment for SDS-PAGE (*UNIT 10.1*), electroblotting (*UNIT 10.7*), and detecting proteins in immunoblots (*UNIT 10.10*)

1. Electrophorese biotinylated experimental protein and protein molecular weight standards in separate lanes on a one-dimensional SDS–polyacrylamide gel (*UNIT 10.1*)

2. Electroblot proteins onto a nitrocellulose membrane (*UNIT 10.7*) and block ~1 hr at 22°C with 3% BSA in PBS.

   Note that the milk-based blocking solution described in UNIT 10.10 should not be used because milk contains free biotin that can lead to unacceptably high backgrounds.

3a. *To visualize biotinylated proteins by labeling with radioactive avidin*: Incubate the blot in 0.5 µCi of ^{125}I-Bolton-Hunter-labeled avidin (Mock, 1990) in 5 ml avidin buffer for 2 hr at 22°C. Wash the membrane extensively in the same buffer without avidin or BSA, air dry, and expose to film (Goodloe-Holland and Luna, 1987).

3b. *To visualize biotinylated proteins with avidin-linked chromophores in the Vectastain ABC kit or ImmunoPure ABC kit*: Follow the manufacturer's instructions.

   The ABC procedure is essentially identical to that described in UNIT 10.10, except that steps 5 and 6 (incubation with a biotinylated secondary antibody) are omitted.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Avidin buffer
150 mM NaCl
4% (w/v) BSA
0.02% (v/v) Triton X-100
50 mM sodium borate
Adjust to pH 10.0 to 10.5 with 1 M NaOH
Store ≤2 months at 4°C

SCU IASI CENTRAL UNIVERSITY LIBRARY

Coupling buffer

Select one of the following buffers (see Critical Parameters for discussion of practical considerations and APPENDIX 2E for recipes):

100 mM $NaHCO_3$, pH 8.5
100 mM Na_2CO_3, pH 8.5
100 mM sodium phosphate buffer, pH 7.5
100 mM sodium phosphate buffer, pH 8.0
100 mM sodium phosphate buffer/5 mM EDTA, pH 8.3

Physiological buffer, pH 7.4

7 g NaCl (120 mM final)
22 ml 0.2 M KH_2PO_4 (*APPENDIX 2E*; 4.4 mM final)
103 ml 0.2 M Na_2HPO_4 (*APPENDIX 2E*; 20.6 mM final)
Add H_2O to 1 liter
Check pH (it should be ~7.4; if not, check concentrations of stock solutions)
Store ≤2 months at 4°C or ≤2 weeks at room temperature

COMMENTARY

Background Information

The extraordinarily high affinity of avidin for biotin was first discovered as the explanation for a deficiency disease caused by ingestion of large numbers of raw eggs. In this disease, which is characterized by skin lesions and growth retardation, the essential vitamin biotin is depleted because it is sequestered by avidin in egg whites (György et al., 1941). The dissociation constant at each of the four biotin-binding sites of avidin is ~10^{-15} M (Green, 1975), making the avidin-biotin interaction one of the strongest known noncovalent biological interactions. Retention of high-affinity binding after derivatization of the biotin carboxyl group with a wide variety of agents has led to the development of numerous assays involving the recovery or detection of biotin-tagged moieties with avidin or other high-affinity biotin-binding proteins described below (reviewed by Wilchek and Bayer, 1990 and Savage et al., 1992).

Selection of biotinylation reagent

There are a number of reagents that can be used for biotinylation (see Table 3.6.1). Selection of reagent depends on the intended uses for the biotinylated product. For instance, most enzyme activities are independent of protein modification on carbohydrate residues, which generally can be assumed to be innocuous; labeling of cysteinyls, however, which generally can be assumed to be innocuous, may disrupt disulfide bonds that are important for structure or activity, so biotinylation of cysteinyls is not recommended for extracellular proteins. Biotinylation of lysyl groups works well with many proteins, including those on surfaces of intact cells, but it also may lead to loss of protein function.

N-Hydroxysuccinimide (NHS) esters of biotin react readily at alkaline pH with any accessible, unprotonated primary amine, such as ε-amino groups of lysyl side chains in proteins (see Basic Protocol 1 and Basic Protocol 2). Because lysine is abundant in proteins, accounting for ~7% of total amino acid residues in an average protein, NHS-biotin and its derivatives (see Table 3.6.1) are the most commonly used biotinylating agents. Modifications of NHS-biotin include addition of a sulfonate group to improve solubility in water (sulfo-NHS-biotin), insertion of a long-chain (LC) spacer arm between the biotin moiety and the reactive ester to increase the availability of the biotin at the protein surface (NHS-LC-biotin), and addition of a cleavable site, such as a disulfide bond (NHS-SS-biotin), to permit release of the protein from biotin using reducing agents such as 2-mercaptoethanol (2-ME) or dithiothreitol (DTT). A cleavable disulfide bond is particularly useful for eluting biotinylated proteins from an affinity matrix containing covalently bound avidin because the exceptionally high affinity (K_d ~10^{-15} M) and correspondingly low off-rate of the biotin-avidin interaction complicates elution with chaotropes (but see below).

Several commercially available reagents (see Table 3.6.1) permit biotinylation of proteins on cysteinyl residues. At physiological pH (pH 7.5 to 8.0), iodoacetyl-LC-biotin, biotin-LC-maleimide, maleimidopropionyl biocytin, biotin-HPDP, and biotin-maleimide all react

BOSTON CENTRAL UNIVERSITY LIBRARY

primarily with free sulfhydryl groups on reduced cysteines. For cytoplasmic proteins, in particular, labeling with cysteine-directed reagents may permit retention of functions lost after derivatization of lysines. However, these reagents may not be advisable for labeling extracellular or membrane proteins with conformations stabilized by disulfide bonds because reduction of at least some disulfides with thiol-reducing agents (e.g., 50 mM DTT or 100 mM 2-ME) is generally necessary for efficient labeling (see Support Protocol 1).

Biotin hydrazides (see Table 3.6.1), especially those with a six-carbon spacer (biotin-LC-hydrazide), can be excellent reagents for biotinylating galactose and *N*-acetylgalactosamine residues on extracellular and transmembrane proteins (see Basic Protocol 4). The biotin hydrazide reagents covalently bind to aldehydes that have been generated from vicinal carbohydrate hydroxyls (*cis*-diols) by mild chemical or enzyme oxidation. The resulting hydrazone bonds are stable between pH 2 and 10. Sodium *m*-periodate provides a fast, effective means for oxidizing *cis*-diols on many soluble proteins, including immunoglobulins. However, the reagent also can react with serines, threonines, and tyrosines. Consequently, periodate oxidation sometimes affects protein biological activity and often alters migration on SDS–polyacrylamide gels. If these side effects cannot be tolerated (e.g., when identifying cell-surface proteins by biotinylation), then galactose and *N*-acetylgalactosamine residues should be exposed and oxidized by treating the cells on membranes with a combination of neuraminidase and galactose oxidase.

Detection of biotinylated proteins

A large number of biotinylated proteins and biotin-detection reagents are commercially available, either as individual compounds or in the form of kits. For instance, biotinylated dipalmitoyl-L-α-phosphatidylethanolamine (Pierce) can be used as a phospholipid tracer in membrane reconstitution studies. Also, biotinylated insulin (Sigma), testosterone (Sigma), and lectins (Pierce or Vector Labs) can be used to identify and/or purify their cellular receptors. Avidin-biotin complex (ABC) detection kits (e.g., Vectastain ABC kit, Vector Labs, and ImmunoPure ABC kit, Pierce; see Support Protocol 2) amplify even weak signals by taking advantage of the multivalency of avidin for biotin and the incorporation of multiple biotins into most biotinylated antibodies and enzymes. Other, similar kits from Vector Labs and Pierce permit visualization of biotinylated proteins on fixed tissue, thin microscopic sections, and microtiter plate wells, allowing use of the biotin-avidin high-affinity interaction in immunofluorescence microscopy, electron microscopy, and enzymatic assays, as well as for protein size determinations.

The molecular masses of experimentally obtained biotinylated proteins are best estimated by comparison with the sizes of biotinylated protein molecular weight markers (Bio-Rad or Vector Labs). Because the addition of one or a few of the small biotin molecules does not significantly increase the mass of most proteins, the sizes of biotinylated protein standards are considered identical to those of prestained or unstained markers. Additionally, the markers are visualized with the same detection methods as the proteins of interest, permitting direct size comparisons.

Nonspecific, biotin-independent binding to avidin can usually be controlled by employing buffers of pH 10.0 to 10.5, which is near the avidin isoelectric point (pI 10.0). Use of such buffers minimizes electrostatic interactions but causes little or no diminution of the avidin-biotin affinity. When high-pH buffers are undesirable, avidin should be replaced either by a neutralized, deglycosylated form of avidin (Neutralite Avidin from Molecular Probes or Southern Biotechnology, or NeutrAvidin from Pierce) or by streptavidin (Pierce, Sigma, and Vector Labs). Streptavidin is a tetrameric protein from the culture broth of *Streptomyces avidinii*; it binds four biotin molecules per mole with an affinity similar to that of avidin. Both neutralized avidin (pI 6.3) and streptavidin (pI 5.0) exhibit fewer nonspecific electrostatic interactions at physiological pH and ionic strength. Streptavidin does, however, contain a sequence that causes biotin-independent binding to integrins and related cell-surface fibronectin receptors under certain conditions (Alon et al., 1990). Many commercially available derivatives of streptavidin (Pierce, Sigma, and Vector Labs) and neutralized avidin (Pierce and Southern Biotechnology) may be used in microscopic and enzymatic assays as a replacement for underivatized avidin.

Recovery of biotinylated proteins

Paradoxically, the high affinity of the biotin-avidin interaction can be a disadvantage during affinity purification of biotinylated proteins. Biotinylated proteins bind tightly to avidin affinity matrices (Molecular Probes, Pierce, Sigma, or Vector Labs) under almost

PCU IASTATE UNIVERSITY LIBRARY

any physiological conditions, but the high-affinity binding is reversed only by harsh denaturants, such as 8 M guanidine·HCl, pH 1.5, or by boiling with 2% (w/v) SDS. Further, the large positive charge on avidin (pI 10.0) and its carbohydrate residues promote nonspecific binding of many negatively charged proteins and some lectins to avidin affinity columns. For this reason, matrices containing bound NeutrAvidin (Pierce) or streptavidin (Molecular Probes, Pierce, Sigma, and Vector Labs) are often used for the affinity purification of biotinylated proteins, despite the significantly greater expense of these matrices.

For preparative purification of biotinylated proteins by affinity chromatography, whether it be on columns containing bound avidin, streptavidin, or neutralized avidin, there are two approaches. The first approach is to accept that the biotin-avidin interaction is essentially irreversible and to attach the biotin label to a dispensable moiety that is left on the column after eluting the protein of interest. For instance, biotinylated monoclonal antibodies can be used to purify individual membrane antigens (Updyke and Nicolson, 1984), and biotinylated insulin and other ligands have been used to purify their specific receptors by avidin or streptavidin affinity chromatography (Kohanski and Lane, 1985/1986; Kraehenbuhl and Bonnard, 1990). Similarly, disulfide bond reduction (see Support Protocol 1) will release proteins that have been biotinylated with NHS-SS-biotin (Chia and Luna, 1989) or with biotin-HPDP (see Table 3.6.1).

The second approach to purifying native proteins is to moderate the avidin-biotin binding affinity by modifying either the bound avidin or the biotin. For example, "monomeric" avidin columns (Pierce or Sigma), generated by treating immobilized avidin with 0.1 M guanidine·HCl, pH 1.5, contain one lower-affinity biotin-binding site (K_d ~5×10^{-8} M) per bound avidin molecule. After presaturating residual high-affinity sites on the column with excess free biotin, biotin-containing proteins can be bound to the columns and then eluted with either 0.1 M glycine, pH 2.0 to 2.8, or 2 mM free biotin (Henrikson et al., 1979; Kohanski and Lane, 1990).

A converse strategy is to derivatize protein lysines with 2-iminobiotin-NHS (see Table 3.6.1), a guanido analog of NHS-biotin that exhibits a strong pH dependence in interactions with avidin and streptavidin (Heney and Orr, 1981). At pH 9.5, iminobiotin binds avidin/streptavidin with characteristically high affinity. However, proteins labeled with iminobiotin can be eluted from avidin columns with either 0.1 M acetic acid or 50 mM ammonium acetate/0.5 M NaCl, pH 4.0. Similarly, columns containing bound 2-iminobiotin (Molecular Probes, Pierce, or Sigma) can be used to purify avidin, streptavidin, and their derivatives. For further information on affinity chromatography, see Chapter 9.

Critical Parameters and Troubleshooting

The most critical aspects of protein biotinylation are the storage and solubilization conditions for the biotinylating reagent. This is particularly critical with NHS derivatives, which contain succinimide ester groups that are very reactive with water. The NHS-biotins should be stored in the presence of desiccant at –20°C, as recommended by the suppliers, and the reagent bottles should be warmed completely to room temperature before opening to minimize condensation. Similarly, it is critical to mix the compounds with the protein to be labeled as soon as possible after dissolving the reagents in aqueous solutions.

Most other parameters are less critical. Although the rate of protein biotinylation is influenced by temperature, short incubations (e.g., 30 min to 1 hr) at either 0° to 4°C or room temperature are usually satisfactory. The extent of biotinylation is determined by the amounts of reagents mixed and the reaction time. Biotin-to-protein molar ratios from 1:1 to 60:1 and reaction times up to 18 hr have been described. Because biotinylation is directed at selected groups in proteins (e.g., labeling ranges from a single cysteinyl or carbohydrate to some or all lysyls, which make up 7 of 100 residues in a typical protein), the choice of biotinylating reagent is often more critical than the reaction conditions. If an enzyme loses activity during biotinylation and if a change of biotinylating reagent is contraindicated, one strategy is to protect the enzyme's active site by adding excess substrate during the biotinylation reaction.

The medium in which biotinylation takes place must be free of components that will interfere with the reaction chemistry. Coupling buffers for NHS-biotin reagents (see Basic Protocols 1 and 2) must be free of ingredients with primary amines. Excess thiol-reducing agent (see Support Protocol 1) must be removed for efficient use of sulfhydryl-directed reagents (see Basic Protocol 3), and excess *cis*-diol-oxidizing agent must be eliminated for labeling of protein carbohydrates (see Basic Proto-

PUBLISHED BY CENTRAL UNIVERSITY LIBRARY

col 4). Finally, pH is an important factor. Lysyl-directed reagents require unprotonated amines (e.g., pH 7.5 to 8.5), whereas maleimide-based thiol-directed reagents undergo side reactions with amines at pH 7.5 or above and thus need more acid conditions (e.g., pH 6.5 to 7.5) if specificity for cysteines is required. Carbohydrate-directed reagents also require acid conditions (e.g., pH 5.5) for specificity.

Reagent solubility may also be a factor. If the protein of interest is sensitive to organic solvents, such as DMF and DMSO, use the water-soluble sulfo-NHS-biotin for labeling lysyl groups. If highest affinity binding is not needed, biotinylating reagents lacking the LC spacer may be more water soluble.

When biotinylating a subset of proteins in a complex mixture—for example, when determining which plasma membrane proteins are accessible to a cell-surface biotinylating reagent—it is useful to include two controls in each experiment. First, some cells should always be carried through the labeling and fractionation procedure in the absence of biotinylating reagent, in order to identify endogenously biotinylated proteins, which are involved in many intracellular carboxylation reactions. Second, to help identify proteins that may be exposed by cell breakage during manipulation, cytoplasmically oriented proteins should be labeled with biotinylating reagent either after deliberate mechanical lysis in the presence of 0.2% (v/v) Triton X-100 or after plasma membrane purification. The group of biotinylated cytoplasmically oriented proteins generated with this control should differ dramatically from that observed after biotinylation of unbroken cells. If the two SDS-PAGE profiles appear similar, then the biotinylating procedure should be repeated under conditions that are less conducive to cell lysis (e.g., biotinylate cells that are still attached to tissue culture plastic).

Because proteins differ dramatically in the number of surface-accessible reactive groups and how they are affected by labeling with a foreign tag such as biotin, it is hard to predict which biotinylating compound will work best for a particular protein. However, biotinylation chemistries are similar to those used for a variety of other compounds, including fluorescent labels. Thus, if a literature reference exists for fluorescently labeling a protein of choice, the most expeditious strategy is to obtain a biotinylating compound with the same reactive group (i.e., succinimide ester, maleimide, or hydrazide moiety) and to follow the published reaction conditions for labeling the protein.

If no information is available about accessible groups or about the functional consequences of a particular derivatization strategy, it is a good idea to try different types of biotinylating reagents at different reagent-to-protein ratios. Reagent/protein molar ratios of 1:1 and 20:1 are usually good starting points. Preliminary characterization of protein functionality should suggest which of the reaction chemistries is superior and whether a higher or lower stoichiometry yields the most efficient labeling.

Anticipated Results

The biotinylation protocols in this unit should biotinylate most proteins. The extent of reaction and the degree to which the protein retains its endogenous structure and activity will vary but may be predictable if other investigators have used a similar chemistry to derivatize the protein with a "tag" other than biotin.

Soluble proteins biotinylated by these procedures have been used as ligands in binding assays in vitro and as tracers for cellular processes including endocytosis, membrane trafficking, and cytoskeletal remodeling (reviewed in Savage et al., 1992, and Wilchek and Bayer, 1990). Cell surface–biotinylated membrane proteins can be used similarly as markers for plasma membrane proteins in biochemical fractionations and in membrane recycling assays. In addition, biotinylated protein(s) can be purified, either alone or in combination with receptors or other binding partners, on avidin or streptavidin affinity columns.

Time Considerations

Labeling reactions involving succinimide esters (NHS-biotin and analogs) and those involving biotin-hydrazides are relatively rapid and usually complete within 1 to 2 hr at 4°C. Reactions of sulfhydryls with maleimides and iodoacetamides are slower, particularly when carried out in lower-pH buffers that optimize reaction selectivity of protein sulfhydryls over amino groups. Although these reactions can be terminated after only 2 to 4 hr, reaction extents are usually increased by longer incubations (e.g., overnight at 4°C).

Similarly, depending on the choice of separation technique, removal of unincorporated biotinylating reagent from labeled protein can be either rapid or slow, with gel-filtration chromatography and centrifugal filtration requiring

UCSF LIBRARY

no more than 1 to 2 hr, whereas dialysis may take 1 to 3 days. Separation steps also are often dictated more by the properties of the protein being labeled than by investigator preference. Some proteins become irreversibly aggregated if subjected to centrifugal filtration; other proteins are denatured or proteolyzed during prolonged dialysis. Here again, it helps to know what other investigators have done successfully with the particular protein under investigation.

CHAPTER 4
Extraction, Stabilization, and Concentration

INTRODUCTION

Sources of proteins to be used for biological assays and for purification purposes are diverse. Recombinant DNA technology has allowed the production of many proteins in forms suitable for biological assays as well as structural analysis; methods for purifying and characterizing proteins from recombinant sources are described in Chapters 5 to 7. In many cases, gene cloning methods lead to the identification and production of proteins even when they have not previously been purified from conventional sources. This type of approach often yields large amounts of protein, which may then be used to generate immunological reagents that can be used in localization studies or to explore the protein's expression patterns in normal tissues or tissue fractions. It remains true that important information about the biological and functional properties of proteins may be inferred from their intracellular distribution and subcellular localization.

For other polypeptides that have not yet been obtained in recombinant form, subcellular fractions may still constitute a convenient, if not the only, source of a protein of interest. Because so many proteins are expressed in a tissue- or cell-type-specific fashion, obtaining the appropriate starting material is not always a trivial matter. Cultured cell lines may, but do not necessarily, express exactly the same protein profile as the tissue that gave rise to the cell lines that happen to be available, and for a number of differentiated cell types no culture methods have yet been described. For this reason, access to subcellular fractions prepared from tissue can be critical. Moreover, the ability to demonstrate the presence or activity of polypeptides of interest in defined subcellular locations and to retrieve them for further study is a key element of protein characterization. Thus methods for fractionating cells, though more commonly considered part of cell biology rather than molecular biology or protein chemistry, remain critical tools in the arsenal of any scientist attempting to isolate and characterize a protein.

The first part of this chapter presents methods for subcellular fractionation of tissues and cultured cells. *UNIT 4.1* discusses a number of basic considerations that should guide the development of specific subcellular fractionation procedures. *UNIT 4.2* provides a number of protocols for preparing the most commonly used subcellular fractions from readily available tissues. Also covered are criteria for assessing the purity of the resulting subcellular fractions and methods for further treatment of membrane fractions to discriminate between integral and peripheral membrane proteins. The details of these protocols apply specifically to the examples described, but are also intended as general guides. The procedures can be modified and optimized for particular applications and for use with a wide range of tissue and cell types. *UNIT 4.3* applies immunochemical methods to obtaining subcellular fractions. These protocols, too, should serve as guides and may be adapted for application to the specific problems at hand.

Most often, the process of protein extraction and purification results in high concentration of low-molecular-weight contaminants. Desalting, buffer exchange, and protein concentration by dialysis and ultrafiltration are discussed in *UNIT 4.4*.

UNIT 4.5 provides a series of tools for the protein chemist that are familiar to many, but have not recently been compiled in an accessible manner: protocols for the selective

BOSTON CENTRAL UNIVERSITY LIBRARY

precipitation of proteins. In many cases, proteins of interest must be recovered from dilute solutions containing protein and nonprotein contaminants. Practical problems for downstream processing may arise because of the volumes to be handled. *UNIT 4.5* offers some practical solutions to these problems.

Overview of Cell Fractionation

Cell fractionation has enjoyed widespread use among cell biologists for half a century. It continues to be a fruitful, if not essential, approach in the reductionistic efforts to define the composition and functions of the multiple compartments in eukaryotic cells. It also provides the essential ingredients for the increasing number of cell-free assays now being used in test-tube reconstructions of complex cellular events involving intercompartmental interactions. Much of the knowledge regarding the composition and function of cell organelles has resulted from fractionation of mammalian tissues, where cells are both abundant and highly differentiated (and thus organelle-rich). However, with new techniques in molecular biology and widened interest in combining studies of intact cells and functional reconstitution, interest in fractionation has spread to cultured cell lines and genetically tractable lower eukaryotic cells.

The goals of cell fractionation often differ depending on the nature of the experiments being conducted. In preparative procedures, in which the intent is to isolate quantities of a particular cell organelle for further study or for subfractionation, the emphasis is on purity and (secondarily) on yield. In analytical experiments, in which the intent is not isolation of organelles but evaluation of associations of selected macromolecules with particular organelles, the emphasis is on using one-step procedures that result in different distributions of various organelles (as defined by marker activities) rather than on separating organelles outright. Finally, in preparing organelles for cell-free reconstitution, the goal is to maintain them in a functional state. The investigator generally has developed a specific assay for intercompartmental interaction that does not rely on organelle purity, so the extent of contamination by irrelevant organelles is less important.

The separation of distinct organelles during cell fractionation results from their differing physical properties—size (and shape), buoyant density, and surface charge density—which reflect their differing compositions. Particular fractionation techniques capitalize on one or more of these properties. For example, gel filtration separates on the basis of size, centrifugation separates on the basis of size and density, and electrophoresis separates on the basis of surface charge density. As knowledge of the specific composition of particular organelles has developed, it has become possible to apply newer techniques such as affinity chromatography and selective density-shift perturbation. In *UNIT 4.2*, examples are given of fractionation procedures based on each of these approaches. Some are preparative and others are analytical. Although an effort has been made to present procedures that are widely applicable and accessible and that do not require highly specialized and expensive equipment, the procedures may have to be modified to adapt them to individual needs. Even isolation of a particular kind of organelle from different tissue or cell sources may necessitate adjustment of fractionation conditions. This also means that in addition to isolating the organelle of interest, you should also plan on confirming the identity of what you have isolated.

Centrifugation is the most widely used procedure in cell fractionation, as indicated in *UNIT 4.2*. It is the only approach commonly used to separate crude tissue homogenates (often having quite large volumes) into subfractions as starting material for more refined purification procedures. Further, the technology available, using rotors with a variety of geometries and diverse media that enable separation according to size, density, or both, now routinely permits refined separations on volumes ranging from submilliliter to several liters. No other technology is this versatile. Gel filtration is limited by the pore sizes of available resins, such that only regularly shaped vesicles with diameters <100 to 200 nm can be purified away from larger or irregularly shaped organelles. Use of electrophoresis for organelle purification, especially at the preparative level, is relatively recent, and, as with gel filtration, its success relies on generating starting material by centrifugation. Although it shows promise for purifying selected organelles (e.g., endosomes) that have been difficult to obtain otherwise, surface charge densities on most organelles may not be different enough (or able to be manipulated sufficiently) to make this a versatile procedure. For these reasons, the remaining comments in this overview focus primarily on fractionation of organelles by centrifugation. For more detailed coverage of each of the topics to be discussed, the reader is referred to the excellent book edited by Rickwood (1984).

BOULDER / PENTRAL UNIVERSITY LIBRARY

BASIC PRINCIPLES OF CENTRIFUGATION

One of the best ways to understand the rationale for various cell fractionation procedures is to examine the Svedberg equation (Equation 4.1.1), which describes mathematically the sedimentation of a spherical particle in a viscous fluid:

$$\frac{dx/dt}{\omega^2 x} = \frac{2r^2(\rho_p - \rho_m)}{9\eta}$$

Equation 4.1.1

where x is the distance from axis of rotation, t is time, ω is the angular velocity, r is the radius of the particle, ρ_p and ρ_m are the density of the particle and medium, and η is the viscosity of the medium.

This equation states that the sedimentation velocity, dx/dt, per unit centrifugal field $\omega^2 x$ (which is set by the instrumentation) increases with the square of the particle radius and the difference in density between the particle and the medium and decreases with increasing viscosity. In practical terms, when sedimentation is performed by differential velocity in a medium such as 0.25 M sucrose, which is less dense than all particles and has a low viscosity, the radius of the particle is the dominant factor that determines the sedimentation rate. In contrast, when isopycnic density gradient centrifugation is used, the density of the medium changes from top to bottom in the centrifugation tube, and the range of densities typically includes the buoyant densities of most particles (vesicles). Thus individual types of vesicles will sediment until $\rho_p = \rho_m$, and the vesicles will then stop at their isopycnic densities. Alternatively, in flotation procedures $\rho_p < \rho_m$ initially and dx/dt is negative, meaning that particles will move toward the axis of rotation (i.e., toward the top of the tube). Evidently, the equation also indicates that sedimentation or flotation, as the case may be, is slowed in media of higher viscosity. As discussed below, various media used in centrifugation are distinguished by their viscosities (and their osmolarities) at high densities.

The Svedberg equation can also be used to discuss three other basic relationships encountered in using centrifugation. First, the velocity of a particle per unit centrifugal field (left side of the equation) is the sedimentation coefficient. Its dimensions are in seconds, and it is generally reported in units known as Svedbergs (S). 1 S = 10^{-13} sec, the same order of magnitude as the sedimentation coefficient of several biological macromolecules (e.g., 5S RNA). Second, the centrifugal field, $\omega^2 x$ is usually normalized to gravity and is expressed in the literature as a relative centrifugal force (RCF = $\omega^2 x/g$). Centrifugation conditions are best reported as $\times g$. RCF is usually expressed at the midpoint of the tube (g_{av}). The centrifugal field term includes the angular velocity in units of radians per second, which is easily converted to revolutions per minute (rpm), the unit most often given in the literature, as follows: RCF = 11.18 $r(N/1000)^2$, where N is rpm. Third, integration of the Svedberg equation over time yields the following relationship (Equation 4.1.2):

$$t = \frac{1}{s\,\omega^2} \ln\left(\frac{X_{max}}{X_{min}}\right) = \frac{k}{s}$$

$$\text{where } k = \frac{1}{\omega^2} \ln\left(\frac{X_{max}}{X_{min}}\right)$$

Equation 4.1.2

This is a measure of the clearance time, the time for a particle of given sedimentation coefficient to travel from the top to the bottom of the tube. Included in k are the geometry of the rotor (X_{max} and X_{min}) and the angular velocity. k-factors are reported in the printed information that accompanies most rotors. They are useful for estimating the length of centrifugation required to pellet a particular particle and for translating centrifugation conditions between two rotors. For a given particle or vesicle, k/t (rotor 1) = k/t(rotor 2).

INSTRUMENTATION

Several pieces of equipment must be available to carry out cell fractionation by centrifugation. These include homogenizers, centrifuges (generally one low-speed and one ultracentrifuge) with compatible rotors, a refractometer for measuring the refractive index of centrifugation media (before centrifugation) and gradient fractions (after centrifugation), a gradient-forming device for generating preformed density gradients, and a gradient-collecting device for unloading the gradients after the run. The refractometer, gradient-forming device, and gradient-collection device are very useful, if not essential, for density gradient and rate zonal sedimentation (*UNIT 4.2*).

Centrifuges. Most organelle purification procedures require that samples be maintained at ≤4°C, so the centrifuges used need to be

BCU IASCE LIBRARY UNIVERSITY

refrigerated. The low-speed centrifuge is used in the early steps of the typical purification procedure for sedimenting large particulates such as nuclei and unbroken cells, frequently from large volumes (e.g., *UNIT 4.2*). The ultracentrifuge is used for subsequent spins at higher speeds and often with smaller volumes. These instruments have a vacuum system as the rotors are spun in an evacuated chamber to reduce friction (and thus heating).

Rotors. Commonly used rotors come in three configurations: fixed-angle, vertical (or near-vertical), and swinging-bucket (Fig. 4.1.1). Continuous-flow and zonal rotors,

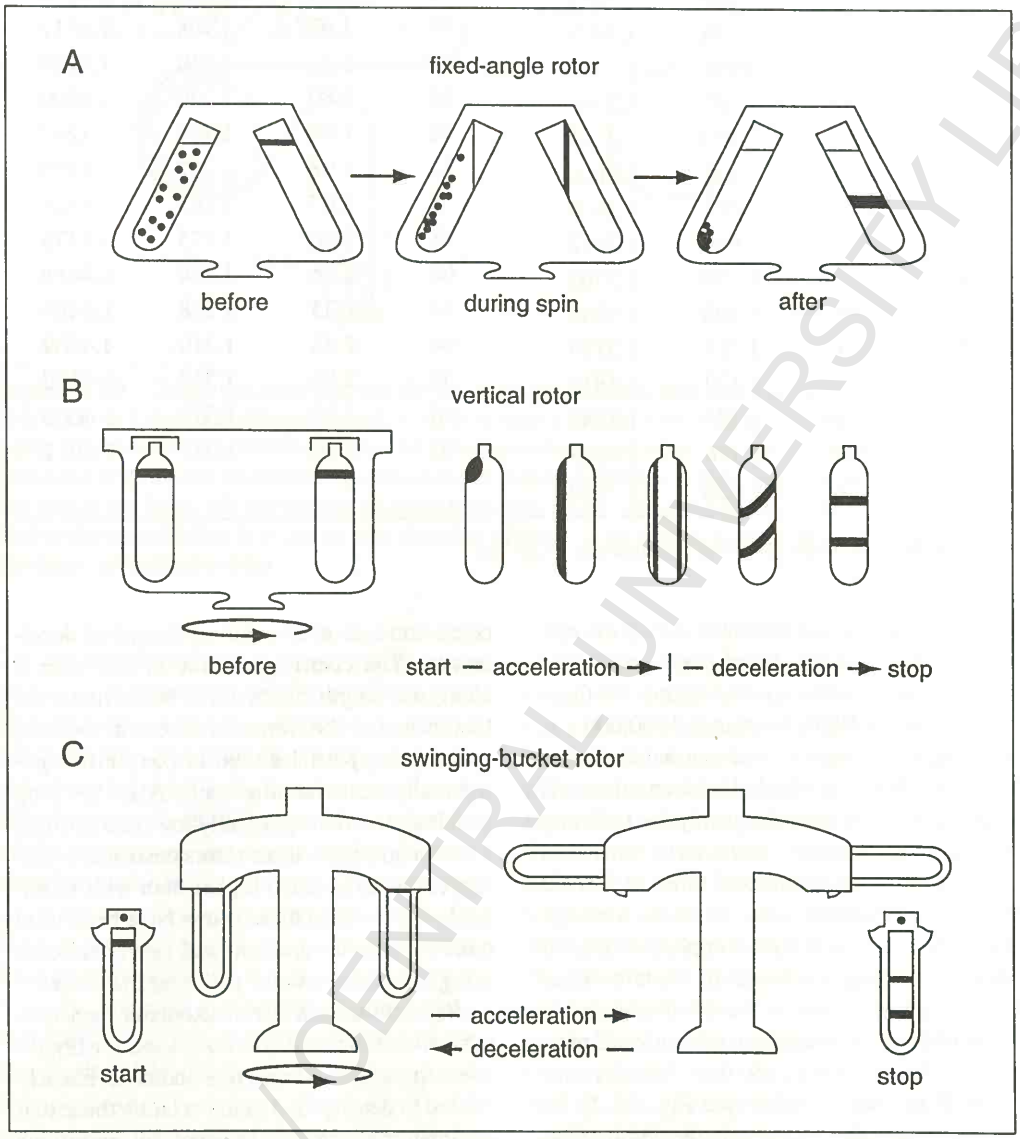

Figure 4.1.1 Rotors used in ultracentrifuges. (**A**) Fixed-angle rotor. In each profile, the tube on the left shows pelleting from a uniform suspension and the tube on the right shows sedimentation of a band layered at the top above a higher-density fluid. Sedimentation is radial (particles move toward the outer wall of the tube and then down this wall to the pellet). Note how the band in the right tube reorients during the spin and then again at the end of the run. (**B**) Vertical rotor. The rotor profile shows tubes with sample layered above a higher-density solution before a run. Note that during the run (successive tube profiles shown at right), the layer reorients along the inner wall of the tube and then the bands resolve vertically. During deceleration the bands reorient to a horizontal position. (**C**) Swinging-bucket rotor. Note the tube on the left in the upper profile has a sample layered at the top. The buckets are mounted vertically on the rotor. During the run, the buckets reorient to the horizontal position, and the bands separate along the length of the tube. Because sedimentation is radial, the particulates in the bands are more concentrated at the walls facing and away from the viewer than in the center of the tube. Toward the end of deceleration, the buckets reorient to the vertical position.

which are loaded and unloaded during the run, are less widely used. Fixed-angle rotors emphasize speed and capacity. Many of these rotors generate RCFs in excess of 600,000 × *g*, meaning low *k*-factors, and can handle a few hundred milliliters of solution at one time. As a result, they are used frequently for pelleting fractions, particularly from large volumes. Most fixed-angle rotors hold tubes in a fixed incline substantially away from the vertical. When the centrifugal force is applied, it is radial rather than along the length of the tube. Thus the path length is across the tilted tube and is reasonably short; particles travel outward until they hit the outer wall and then "slide" down the wall to form a pellet (see Fig. 4.1.1). In vertical rotors, the path is only the width of the tube. As is evident from the figure, in both fixed-angle and vertical rotors the solution in the tubes reorients from the horizontal to the vertical during acceleration and reverses during deceleration. These rotors can be advantageous for density gradients (*UNIT 4.2*) because equilibrium is reached quite rapidly with the short path, and the separation of bands of different density increases as the contents of the tube reorient during deceleration. With swinging-bucket rotors, the tube and its contents reorient from vertical to horizontal during acceleration and reverse during the end of deceleration. The centrifugal force in this case is along the length of the tube. Note, however, that because the force is directed radially, sedimenting particles tend to concentrate peripherally near the tube walls. Also, the long path length and the generally lower centrifugal forces required for these rotors mean that *k*-factors are usually much higher than with fixed-angle rotors. Thus these rotors have been used more for density gradient and rate zonal centrifugations and less for pelleting fractions.

Refractometers. A refractometer measures refractive indices of solutions used for organelle separations. Refractive index is linearly related to density, and tables relating these two parameters over a large range of concentrations have been prepared for sucrose (Table 4.1.1) and are readily constructed by weighing aliquots of other accurately prepared gradient solutions. The measurement of refractive index/density is particularly useful for characterizing the position of organelles in gradients after centrifugation and for ensuring reproducibility of gradients from one experiment to another.

Gradient-forming devices. These devices consist of two chambers with an interconnecting channel along the bottom and an outlet from

BCU IASH CENTRAL UNIVERSITY LIBRARY

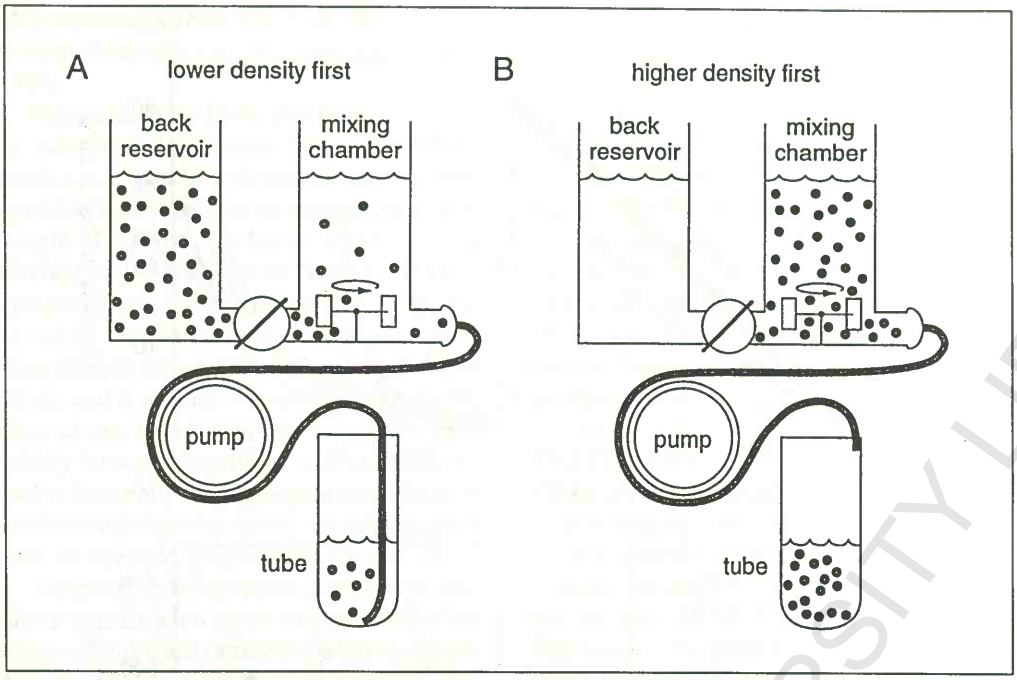

Figure 4.1.2 Linear gradient-forming device showing the back reservoir connected to the mixing chamber via a channel with a stopcock. A delivery tube leads from the mixing chamber to a peristaltic pump and then to the centrifuge tube. (**A**) Configuration used when the lower-density solution is delivered first; the lower-density solution is in the mixing chamber and the outlet is at the bottom of the centrifuge tube. (**B**) Configuration used when the higher-density solution is delivered first; the higher-density solution is in the mixing chamber and the outlet tube is always above the surface of the liquid entering the tube.

one chamber that connects to a peristaltic pump on its way to the centrifuge tube (see Fig. 4.1.2). The channel is gated by a stopcock. For linear gradients (the type most frequently used), the chambers have the same cross-sectional area. Solutions representing the extremes in density of the desired gradient are each placed in one chamber, and a stirring device is placed in the chamber with the outlet going to the tube. As fluid is pumped out of the mixing chamber, fluid also flows through the connecting channel from the reservoir to maintain the same pressure head in the two chambers. Consequently, the density of the solution in the mixing chamber progressively changes. Gradients can be generated either highest density first, if the higher-density solution is placed in the mixing chamber, or lowest density first, if the lower-density solution is placed in the mixing chamber. Note that for highest density first, the delivery point must be located above the level of the solution filling the centrifuge tube, whereas for lowest density first, the delivery point must be at the bottom of the tube.

Gradient-collection devices. Gradient collection at the end of centrifugation requires a systematic and reproducible means of emptying the tube. Gradients can be collected from the top or from the bottom. With care, a pipettor (e.g., Pipetman, Rainin) of suitable volume can be used for manual collection from the top, taking care to withdraw the equal-volume fractions from just below the meniscus. Alternatively, Buchler markets a pumping device (Autodensiflow) that continually adjusts to the height of the meniscus and withdraws gradients from the top, and both MSE Scientific and Nyegaard market devices that pump high-density solution beneath the gradient and progressively displace the gradient, which is again collected at the top. For collection from the bottom, the centrifuge tube is punctured with a needle and the gradient is collected dropwise.

FRACTIONATION MEDIA

Early in the development of centrifugation as a tool for purification of cellular organelles, it was established that nonelectrolyte-based media are preferable to electrolyte-based media for reducing organelle aggregation (Hogeboom et al., 1948). Most media used today are nonelectrolyte-based, although some do have a substantial electrolyte content (e.g., STKM medium, which contains 50 mM

BU MEDICAL CENTRAL UNIVERSITY LIBRARY

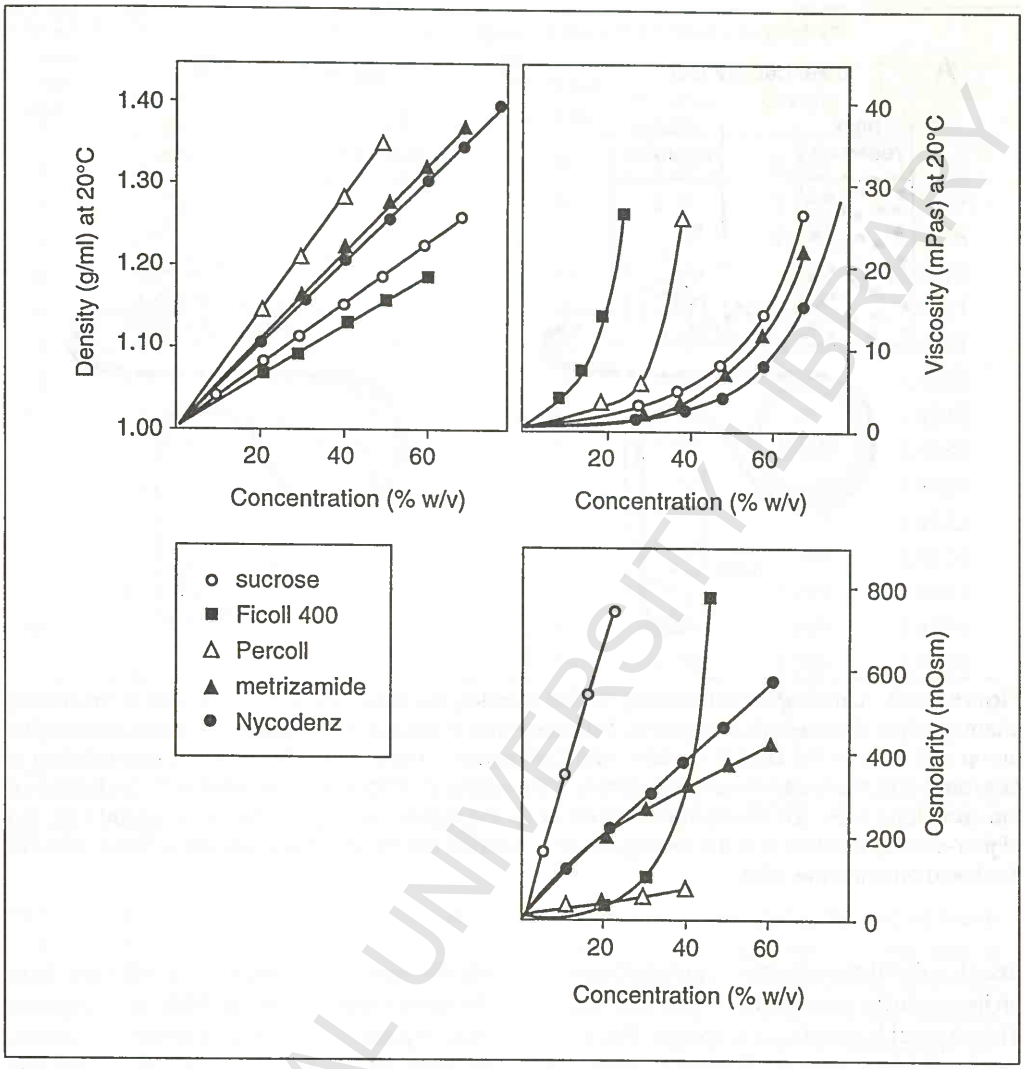

Figure 4.1.3 Plots of density, viscosity, and osmolarity of gradient media used to fractionate cellular organelles as a function of concentration. Data are shown for sucrose, Ficoll 400, Percoll, metrizamide, and Nycodenz. Modified from Rickwood (1984) by permission of IRL Press.

Tris·Cl, 25 mM KCl, and 5 mM $MgCl_2$ in addition to 0.25 M sucrose; Adelman et al., 1973). Moreover, media are generally isoosmotic or hyperosmotic as compared to 0.15 M NaCl. Organelles are osmometers, with water moving across their limiting membranes to maintain osmotic equilibrium; thus lysis can occur in hypoosmotic media.

The nonelectrolyte solute most commonly used in subcellular fractionation is sucrose. High-quality sucrose (free of RNase) is reasonably inexpensive, very soluble, and can be used readily to prepare solutions that span the range of densities of most biological organelles (Table 4.1.1). In addition, procedures have been developed for purifying most biological organelles in sucrose. Sucrose, however, has limitations; at higher concentrations solutions are quite viscous and hyperosmotic. Isoosmotic sucrose (0.25 M; ~9% w/v) has a density of only 1.03 g/ml, which is at the lower-density end for biological organelles. Thus all isopycnic density gradient centrifugation performed in sucrose constitutes hyperosmotic conditions; intraorganellar water redistributes to the surrounding medium, and the organelles shrink and increase in density. These changes are reversible for some, but not all, organelles.

Various sugar alcohols have been used in place of sucrose in some procedures. Glycerol is one, but although its viscosity is lower than that of sucrose, so is its density at a given concentration, and it also permeates some organelles. Mannitol has been used in a few procedures where the use of sucrose is not feasible—e.g., for isolation of epithelial brush border membranes that contain sucrase (Malathi et al., 1979)—and sorbitol has been a favorite

PCU IASRI CENTRAL UNIVERSITY LIBRARY

for fractionating yeast, which secrete invertase (a form of sucrase; e.g., Walworth and Novick, 1987).

Polysaccharides have also been employed as substitutes for sucrose. Ficoll 400 (Pharmacia), a chemical polymer of sucrose with epichlorohydrin that has an average molecular weight of 400,000, has been a popular choice (70,000 is also available, as Ficoll 70). At low concentrations, it has very low osmolarity, but as can be seen in Figure 4.1.3, the osmolarity rises sharply above 30% (w/v; density ~1.09 g/ml), and it is quite viscous at all concentrations above 10% (w/v). Ficoll has been used widely for separating different cell populations and is frequently most useful as an additive to media containing other density-modifying agents (see, for example, the procedures in *UNIT 4.2*).

Iodinated nonelectrolytes increase the density of fractionation media through most of the range of biological organelles while maintaining reasonably low viscosity and osmolarity as compared to sucrose. Two popular and closely related compounds are metrizamide and Nycodenz (both marketed by Nyegaard; Accurate Chemical—listed in the *SUPPLIERS APPENDIX*—is the U.S. outlet). The structures and specific application of these reagents are discussed in more detail, along with the procedure for their use, in *UNIT 4.2*. As seen from Figure 4.1.3, 40% (w/v) solutions of both metrizamide and Nycodenz have a density >1.2 g/ml (above that of most organelles) and an osmolarity ≤400 mOsm with reasonable viscosity. With all these advantageous features, why aren't they used more? They are rather expensive, which certainly limits their use for large-scale work. In addition, they absorb in the UV and have been reported to inhibit selected enzyme activities (see *UNIT 4.2*).

A different alternative for achieving high densities at low viscosity and osmolarity involves the use of Percoll, colloidal silica coated with polyvinylpyrrolidone to reduce its adsorption to biological organelles. For fractionation of cellular organelles, Percoll is almost always used in combination with isoosmotic sucrose, because pure Percoll is only 10 mOsm. As can be seen from Figure 4.1.3, Percoll-containing media can achieve very high densities with reasonably low viscosities. Because Percoll particles have a significant size (range 30 to 150 Å) and density, they sediment during centrifugation. Thus, concentration gradients self-form fairly rapidly during a spin and the profile of density along the length of the tube continuously changes with time (see Fig 4.2.2). As pointed out in *UNIT 4.2*, the shallow gradients achieved with Percoll can be very advantageous in separating organelles having densities that differ only slightly; however, for reproducibility, the conditions of centrifugation must be quite carefully set. Percoll also has its limitations: it absorbs in the UV, interferes with protein assays, precipitates in acid and organic solvents [do *not* attempt to precipitate Percoll-containing fractions with trichloroacetic acid (TCA) or acetone], and is difficult to get rid of entirely. Some strategies for removing Percoll are discussed in *UNIT 4.2*.

EVALUATION OF FRACTIONATION

In setting up a procedure for separating or purifying cellular organelles, it is advisable to evaluate the steps of the protocol to confirm that the outcome is as desired and as stated. This means setting up assays for marker activities and protein and accounting for the totality of both throughout the procedure. This meticulousness enables the investigator to evaluate the homogenization, yield, fold purification, and extent of contamination by other undesirable organelles, and to account for 100% of the activity at each step. The extent of cell breakage during homogenization can be estimated by determining the fraction of a marker activity of a particular organelle that pellets in the first low-speed centrifugation step (and is likely still to be associated with unbroken cells), while the extent of organelle breakage can be estimated by determining the fraction of the total amount of a soluble intraorganellar protein that is not sedimented by a high-speed spin that pellets all of the organelle. Following marker activity throughout purification enables the investigator to determine the yield of the desired organelle, and, if markers of other organelles are followed, the extent of residual contamination. Finally, if protein concentration is determined in parallel, calculation of the ratio of activity to protein (known as specific activity) at each step provides an estimate of fold purification or enrichment. In the event that analytical rather than preparative procedures are used, determination of marker activity in every fraction is essential for specifying the distribution of a particular organelle. Finally, it is very important to note that subcellular fractionation is never perfect! The entirety of a particular organelle is never obtained in completely pure form. In fact, the term "fraction" signifies both incomplete yield and incomplete purity. The careful investigator will always be cognizant

of the limitations of the procedures and the consequent limitations of the results.

DEFINITIVE PROCEDURES

A useful starting point in isolating a particular cellular organelle may be to examine a procedure that has been designed for the specific organelle of interest. Table 4.1.2 lists references to procedures for purifying most of the membranous organelles found in eukaryotic cells (several are also presented as protocols in *UNIT 4.2*). Unfortunately, it is not possible to make this listing comprehensive, but the procedures selected have achieved unusually good purity and in many cases have documented their achievement by bookkeeping of marker activities. Although several of the procedures are reasonably old, they have been used either as starting points for subfractionation (e.g., nucleus, endoplasmic reticulum, secretion granules, plasma membranes, lysosomes, mitochondria, and peroxisomes) or for functional studies in cell-free assays (e.g., Golgi, endoplasmic reticulum, and mitochondria).

Purification of Organelles from Mammalian Cells

The protocols in this unit illustrate a range of different procedures that have been used to fractionate tissue homogenates. They emphasize different fractionation techniques that have been used for rat liver, an abundant tissue that has been a favorite of many investigators and has served as the source of many organelle preparations of excellent purity. For selected procedures, other examples have been given using other tissue sources (e.g., glandular tissues that maintain protein storage granules for regulated secretion) or, where particularly favorable, cultured cells.

The basis (or goal) of each separation and the merits and limitations of each procedure are summarized in Strategic Planning; this section serves as a guide for selecting among the various approaches (see Background Information for more in-depth discussion). In Strategic Planning the methods are described in somewhat general terms, but each corresponding protocol includes specific details relevant to a particular sample cell type (and in many cases a particular organelle).

STRATEGIC PLANNING

Because there are so many different techniques available for purifying organelles, the following annotated outline has been prepared as a guide to selecting a purification strategy.

Differential Centrifugation by Velocity (see Basic Protocol 1)

Basis/Goal

Enrichment of organelles largely according to size by serial spins of increasingly higher force and longer time.

Merits

1. This is the nearly universal starting point in fractionation of a homogenate to remove unbroken cells and large debris (as well as nuclei, if not desired).
2. The procedure is the best way to concentrate organelles of a particular size range from large volumes for use as starting material for subsequent procedures.
3. It is generally performed in isoosmotic sucrose medium, thus providing the best chance of organelles retaining function in subsequent cell-free assays.
4. It is useful for sedimenting macromolecular assemblies, e.g., microtubules polymerized from organelle-free postmicrosomal supernatant.
5. The separation is simple to perform. Within limits, successive resuspension and recentrifugation can be used to further enrich a pellet for a given size range of organelle.

Limitations

1. Pelleted fractions are nearly always substantially contaminated with smaller organelles.
2. Aggregation of organelles in pellets can be significant and difficult to reverse, especially if medium has a substantial electrolyte content.

BOU IAS / CENTRAL UNIVERSITY LIBRARY

Differential Centrifugation by Equilibrium (see Basic Protocol 2)

Basis/Goal
Separation of organelles according their distinct buoyant densities by centrifuging to equilibrium in a density gradient.

Merits
1. The technique provides an excellent follow-up to differential centrifugation by velocity (Basic Protocol 1) for resolving similar-sized organelles into subpopulations of distinct densities.
2. Use of this procedure is often advantageous for complex mixtures resolved as multiple bands.
3. It is also useful for analytical experiments in which the distribution of organelles (or co-distribution of proteins with particular organelles) is being examined, and for preparative experiments to obtain purified organelles for further study.

Limitations
1. Extended centrifugation times may be detrimental to labile activities.
2. Quantities of sample loaded on each gradient must usually be low to maintain high resolution and avoid aggregation.

Rate Zonal Centrifugation Using Sucrose (see Alternate Protocol 1)

Basis/Goal
Resolution of organelles from a loading layer (most often at the top of the tube) into enriched zones within a density gradient; separation based on size, shape), and density.

Merits
1. The procedure provides multiparameter separation within a single run, which is especially advantageous for analytical experiments that rely on different distributions for several organelles.
2. It is widely used for separations of macromolecules and macromolecular assemblies in addition to membrane-bounded organelles: e.g., proteins of different molecular weights (either water-soluble proteins or detergent-solubilized membrane proteins); polysomes of different length.

Limitations
1. Organelle/protein content of the sample loaded must be kept reasonably low for best resolution; aggregation may be a problem with overly large loads.
2. Its main value is in analysis of organelle distribution; use in organelle purification generally requires further steps.
3. Hyperosmotic high-density sucrose solutions may cause organelle shrinkage due to water efflux, and can thereby reduce density differences between certain types of organelles.

Gradient Fractionation Using Percoll (see Alternate Protocol 2)

Basis/Goal
Rapid separation largely by density in an isoosmotic self-forming density gradient.

CU IAST CENTRAL UNIVERSITY LIBRARY

Merits

1. Percoll's negligible osmolarity but high density and modest viscosity allow its use as an additive to sucrose for achieving a very wide range of densities under isoosmotic conditions.
2. Because Percoll itself sediments appreciably during centrifugation, self-formed density gradients continually change shape during the run. Initially, they are very shallow along most of the length of the tube, allowing excellent separation of organelles that have only slightly different densities and that approach isopycnic density rather rapidly. Large organelles with slightly differing densities can be easily resolved in fixed-angle rotors, whereas small organelles with slightly differing densities can be resolved in vertical rotors (where the short path length during the run reduces the time needed to achieve equilibrium).
3. Equilibrium density separations require relatively short centrifugations, especially compared to those in high-density sucrose.
4. The procedure can be used effectively for large-scale organelle purification, especially where the organelle of interest has either a lower or a higher density than all other organelles in the starting mixture.

Limitations

1. In general, Percoll is not very suitable for generating distinct distributions for several different organelles in the same centrifuge run. With a gradient profile featuring a shallow central segment between steep extremes, low-density organelles tend to concentrate together at the top of the gradient while high-density organelles tend to concentrate together at the bottom of the gradient.
2. Thoroughly removing Percoll from a purified fraction is a major challenge (see Critical Parameters for further discussion).
3. Further limitations may be imposed by the organelles themselves. Certain organelles may have heterogeneous sizes, shapes, and densities; thus, portions of one type of organelle may end up at both extremes of the gradient.

Gradient Fractionation Using D_2O (see Alternate Protocol 3)

Basis/Goal

Separation by density gradient with heavy (deuterated) water substituted for normal water.

Merits

1. There is reduced osmolarity and viscosity of fractionation medium.
2. It is mainly used in analytical procedures.

Limitations

1. The procedure is quite expensive due to the cost of D_2O, limiting its preparative use.
2. Partial exchange of D_2O for H_2O occurs within membrane-bounded organelles, with the extent of exchange differing among organelles. This may either enhance or reduce their separation and requires empirical analysis.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Gradient Fractionation Using Nonionic Iodinated Solutes (see Alternate Protocol 4)

Basis/Goal

Separation by density gradient with iodinated nonelectrolytes substituted for sucrose to achieve high density.

Merits

Substituting nonionic solutes for sucrose makes it possible to prepare media that span the range of densities of all membrane-bounded organelles, yet have quite low viscosities and only moderate osmolarities. For organelles with a high buoyant density, this significantly reduces efflux of water, which can lead to irreversible changes in some organelles.

Limitations

1. The biggest limitation to these very promising media—metrizamide and Nycodenz—is their expense, which prevents most labs from using them for routine large-scale fractionation.
2. Selected enzymes are inhibited by these media but most are not; see Alternate Protocol 4 (explanatory Note preceding the protocol).
3. It is important to keep in mind that these media absorb in the UV range.

Gel Filtration to Isolate Secretory Vesicles (see Basic Protocol 3)

Basis/Goal

Purification of small, homogeneous vesicles from larger and/or irregularly shaped organelles.

Merits

1. The procedure offers excellent resolution for purifying some of the smallest membrane-bounded organelles.
2. It is a promising analytical technique for demonstrating specific association of selected proteins with small vesicles.
3. It is very useful for characterizing or purifying protein complexes, e.g., the cytosolic macromolecular assemblies that function in membrane coat formation during vesicular trafficking.

Limitations

1. Separation is limited to organelles that are small enough to enter the pores of the gel filtration resin efficiently. As indicated by examples cited in the protocol, this means vesicles <200 nm diameter.
2. As the separation is based on size alone, gel filtration with the available resins will not distinguish different types of small vesicles having the same size.

Preparative and Analytical Electrophoretic Separation (see Basic Protocol 4 and Alternate Protocol 5)

Basis/Goal

Separation of small organelles and macromolecular assemblies on the basis of distinct surface charge densities.

Merits

1. Although electrophoretic separations have not been used widely in organelle purification, the preparative technique (Basic Protocol 4) shows substantial promise

CU IAS / CENTRAL UNIVERSITY LIBRARY

because it is reasonably easy, not expensive, and as reported by its originators (L. Rome, pers. comm.) is capable of handling relatively large samples (i.e., 50 mg protein). Furthermore, preliminary findings suggest that larger-porosity agarose gels might be applicable in the separation of organelles up to 300 nm in diameter.

2. The analytical procedure (Alternate Protocol 5) requires a free-flow electrophoresis chamber, either commercial or constructed as described by Tulp et al. (1993); the latter can be done for only a minor fraction of the cost of the commercial apparatus. The impressive separations that have been reported (Tulp et al., 1994) make this device worthy of serious consideration. Alternatively, electrophoretic analyses of synaptic vesicles (Carlson and Kelly, 1978) have been performed on Ficoll gradients in plastic tissue culture pipets.

Limitations

Use of these procedures has been limited to work on coated vesicles or endosomes/lysosomes; therefore, their applicability would need to be tested before they could be applied to other organelles.

Solid-Phase Immunoadsorption (see Basic Protocol 5)

Basis/Goal

Isolation of vesicles or macromolecular assemblies using specific antibodies attached to solid-phase supports.

Merits

1. The technique is very promising and highly selective.
2. It can be used both analytically and preparatively. Solid phases include fixed *S. aureus*, protein A–Sepharose, and secondary or primary antibody coupled to several types of beads (e.g., Sepharose, Eupergit, magnetic) or other polymers.
3. Co-localization of components on immunoadsorbed vesicles can be demonstrated secondarily by immunochemical or immunocytochemical procedures (e.g., see Laurie et al., 1993).

Limitations

1. Immunoadsorption requires a specific antibody that can bind to an exposed epitope on the surface of the organelle (or macromolecular assembly). The success of the technique depends on the quality of the antibody (specificity and avidity) and accessibility of its epitope; adsorption of vesicles derived from intracellular compartments requires cytosolically exposed epitopes, whereas adsorption of plasma membrane vesicles (which generally vesiculate with the ectodomain outward) requires epitopes on the extracellular surface.
2. Although sensitivity is generally a positive quality, in immunoadsorption it can be a limitation. Vesicle binding via an avid antibody may require only a few antigen-antibody interactions. As many membrane proteins are not confined to single compartments but instead traffic among compartments, immunoadsorption may not necessarily isolate only a single type of compartment.

Purification by Lectin Adsorption (see Basic Protocol 6)

Basis/Goal

Isolation of vesicles derived from plasma membrane by lectin binding to exposed oligosaccharides.

SCU IRSC / CENTRAL UNIVERSITY LIBRARY

Merits

1. The procedure takes advantage of the unique orientation (ectodomain outward) of plasma membrane vesicles. Exposed glycoproteins on these vesicles can bind to immobilized lectins, particularly wheat germ agglutinin (WGA).
2. The procedure is organelle-specific and quite simple as there is limited need for preenrichment steps.
3. *N*-acetylglucosamine used to elute vesicles from WGA is inexpensive.

Limitations

1. The procedure is largely specific for a single type of membrane.
2. Separation is only as good as the uniformity of orientation of vesiculated membranes. Intracellular vesicles with inverted orientation can potentially bind to WGA, and inverted plasma membrane vesicles will be unable to do so. Respectively, these occurrences will increase contamination and reduce yield. Generally, however, the orientations are fairly uniform, so this does not pose a major problem.
3. Although the purification of plasma membrane is excellent using the protocol presented here, in other procedures it has been observed to be less extensive; possibly adsorbed vesicles or cytoskeletal proteins increase the contamination.

Density Shift Using Digitonin (see Basic Protocol 7)

Basis/Goal

Analytical procedure in which binding of digitonin to cholesterol increases the buoyant density in proportion to the cholesterol content of the membrane. Density shifts determined following equilibrium centrifugation range from zero (for ER and mitochondria, which have no resident cholesterol) to intermediate (Golgi cisternae) to maximal (post-Golgi membranes, including the plasma membrane).

Merits

An excellent procedure for distinguishing the possible association of a newly identified (or newly synthesized) protein with a particular compartment, using the extent of density shift of compartmental markers for correlation.

Limitations

Correlation of distributions is a good supporting technique but does not directly demonstrate a particular association.

Density Shift Using Colloidal Gold Conjugates (see Basic Protocol 8)

Basis/Goal

Capitalizes on the high density of colloidal gold and the well-established characteristics of receptor-mediated endocytosis to provide density modification of selected endocytic compartments, thereby enabling their purification.

Merits

1. Although this procedure has not been used widely, it appears quite promising for studies aimed at characterizing the various compartments comprising the endocytic network.
2. The density shifts observed are substantial, making this a good preparative method,

ACU IAS / CENTRAL UNIVERSITY LIBRARY

and the procedure can be tailored to specific pathways based on the choice of the ligand that is conjugated to colloidal gold.

Limitations

1. Preparation of the gold conjugates is fairly lengthy, but the procedures involved are not difficult.
2. Procedures are limited to cells or tissue where it is possible to introduce endocytic tracers efficiently.
3. The purity of the fractions obtained is limited by the ability to achieve selective compartmental labeling. No endocytic tracers are perfect compartment markers; thus density shifts are likely to spill over into sequential compartments.

Extraction of Extrinsic Proteins from Membranes Using Sodium Carbonate (see Basic Protocol 9)

Basic/Goal

Stripping of extrinsic (or adsorbed) proteins from membrane vesicles in order to distinguish candidate integral membrane proteins as those that remain membrane bound.

Merits

1. Widely used analytical tool to distinguish membrane proteins anchored in the lipid bilayer either by transmembrane segments or by lipid tethers (e.g., prenylation).
2. Frequently a complementary procedure to phase partitioning in the nonionic detergent Triton X-114 (Bordier, 1981).

Limitations

1. The extreme pH may denature proteins of interest; this possibility should be tested on an individual basis.
2. Membrane vesicles develop discontinuities during treatment (see Fujiki et al., 1982), so subsequent procedures should not require intact vesicles.

DIFFERENTIAL CENTRIFUGATION BY VELOCITY

BASIC PROTOCOL 1

This is the classical standard method of cell fractionation using centrifugation, often used as the starting point for a more complex purification procedure. A cell homogenate is subjected to serial centrifugations of increasingly higher force and longer duration, generally in isoosmotic (0.25 to 0.3 M) sucrose medium (see Background Information for discussion of sucrose concentration). Resulting gradient bands (concentrated fractions consisting of organelles of particular sizes) are suitable as starting material for further purification or other procedures. This method gives relatively low resolution in that it does not yield fractions of high purity. However, the postnuclear supernatant (PNS) from step 6 and the supernatant from step 8 serve as useful starting materials for procedures that yield high-purity fractions mainly by exploiting differences in organelle density.

As an example of the approach, this protocol presents the fractionation of rat liver into various components, including mitochondria, microsomes, and a largely organelle-free "cytosol" fraction. Additional steps for using tissues other than liver are included.

BCU ARTS CENTRAL UNIVERSITY LIBRARY

Materials

Rat starved overnight and freshly sacrificed
Homogenization medium: 0.25 to 0.3 M sucrose plus optional additives (see recipe; if PMSF is included, add just before use)

Motor-driven pestle with high-torque motor (e.g., Baxter)
Cheesecloth
Tubes suitable for low-speed centrifugation: 1.5-ml microcentrifuge tubes (for small-scale preparation) or 15- or 50-ml graduated screw-cap tubes (for larger-scale preparations)
Low-speed centrifuge capable of producing a 600 × *g* centrifugal field, 4°C
Teflon-glass homogenizer (A.H. Thomas or equivalent) of appropriate size for the scale of the experiment: type AA (1 ml) up to type C (40 ml)
200-µm mesh nylon screen (Tetko)
Dounce-type glass homogenizer
Polycarbonate or polyallomer tubes suitable for ultracentrifugation (e.g., 3-ml size to fit Beckman TLA-100.3 rotor) or polycarbonate bottle assemblies (e.g., 10-ml size to fit Beckman 50Ti rotor or 25-ml size to fit Beckman 60Ti or 70Ti rotor)
Ultracentrifuge and fixed-angle rotor appropriate to the scale of the experiment (e.g., Beckman 50Ti, 60Ti, or 70Ti) or tabletop ultracentrifuge and rotor (e.g., Beckman tabletop with TL100 rotor)

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after removing and weighing tissue should be conducted at 0°C (ice bucket) or 4°C (cold room).

Homogenize the sample

1. Remove liver from a freshly sacrificed rat that has been fasted overnight (to deplete hepatic glycogen). Keeping the liver on ice as much as possible, weigh and then mince coarsely with scissors or razor blade in the weighing boat.

   Stored frozen tissues are not satisfactory for most organelle purification procedures.

2. Homogenize the minced liver at 20% (w/v) in homogenization medium using five up-down strokes at 1700 rpm with a high-torque motor-driven pestle.

3. Filter the homogenate through four layers of cheesecloth.

Perform low-speed centrifugation to remove nuclei and larger particulates

4. Transfer the homogenate to tubes suitable for low-speed centrifugation and centrifuge 10 min at 600 × *g* (1700 rpm for a 20-cm-radius rotor), 4°C.

   For small-scale procedures, this centrifugation can be performed in 1.5-ml microcentrifuge tubes for 40 sec at 10,000 rpm (6600 × g).

5. *For tissues such as pancreas and salivary gland:* Resuspend the pellet in the original volume of homogenization medium and rehomogenize with the Teflon-glass pestle, then centrifuge again under the same conditions. Combine the resulting supernatant with the supernatant from the first centrifugation, filter through 200-µm mesh nylon screen, and disperse by 3 to 4 strokes in a Dounce homogenizer.

   Pancreas and salivary gland (and some other tissues) are more difficult to homogenize than liver. Homogenization is one of the key steps in successful organelle purification procedures, so it is important to employ the two-step homogenization procedure when appropriate.

6. The pellet is the crude nuclear fraction and the supernatant (or combined supernatants,

UCU IAS / CENTRAL UNIVERSITY LIBRARY

for optional two-step homogenization) is the postnuclear supernatant (PNS) fraction. Aspirate any lipid that has accumulated at the surface of the PNS, then withdraw the PNS, taking care to leave the pellet undisturbed. Transfer the PNS to polycarbonate tubes that are suitable for ultracentrifugation.

Prepare mitochondrial and microsomal fractions by successive ultracentrifugations

7. Centrifuge the PNS 30 min at 10,000 × *g* (e.g., 10,000 rpm in Beckman 50Ti, 60Ti, or 70Ti), 4°C, to pellet the mitochondrial fraction.
8. Remove the supernatant and transfer to clean polycarbonate ultracentrifuge tubes.
9. Resuspend the mitochondrian-rich pellet and transfer to a Dounce homogenizer. Disperse the pellet into a fine suspension by several manual strokes.

   The pellet also contains lysosomes and peroxisomes (which are much less abundant) and small amounts of rough and smooth microsomes that have happened to pellet.

10. Optionally, further purify the mitochondria away from smaller-sized contaminants by repeating steps 6 and 7.

    This strategy has been used by Carvalho-Guerra (1974) for preparing liver mitochondrial fractions.

11. Centrifuge the supernatant from step 7 for 2 hr at 100,000 × *g*, 4°C, in fixed-angle rotor.
12. The resulting pellet is the total microsomal fraction, consisting of vesicles derived from rough endoplasmic reticulum and various smooth-membrane-bounded organelles (including fragments from mitochondria and larger-sized organelles that were damaged during homogenization). Remove the postmicrosomal ("high-speed") supernatant; this is generally used as "cytosol" in various assays.
13. Resuspend the microsomal pellet in an appropriate buffer for assays or additional purification, disperse by Dounce homogenization, and save at 4°C until further use.

DIFFERENTIAL CENTRIFUGATION BY EQUILIBRIUM

BASIC PROTOCOL 2

This procedure can be used alone (as presented here) but most often is used as a follow-up to differential centrifugation by velocity (Basic Protocol 1). Typically, the samples are applied above (or beneath) a sucrose or other nonelectrolyte-based medium having a density that varies—either discontinuously (in steps) or continuously—from top to bottom of the tube. The sample must of course be lower yet in density than the lowest density of the gradient (if applied to the top) or higher than the highest density of the gradient (if applied at the bottom). During centrifugation, organelles sediment (or float) until reaching their isopycnic positions, where the buoyant density of the particle equals the density of the medium (*UNIT 4.1*). In a continuous gradient organelles separate as bands distributed throughout the gradient; in a discontinuous gradient the organelles concentrate at the interfaces between the particular steps whose densities are lower and higher than that of each organelle. A continuous gradient is preferred for fractionating complex mixtures containing several different organelles.

As an example of this type of fractionation, the following one-step procedure (taken from Bergeron et al., 1982) describes separation of fractions from homogenates of rat liver by flotation in a continuous sucrose gradient. Specific information about collecting Golgi fractions (the goal of Bergeron's work) is described in annotations.

CHILE
BOSTON CENTRAL UNIVERSITY LIBRARY

Additional Materials (also see Basic Protocol 1)

Rat starved overnight and freshly sacrificed
Sucrose media: 0.25 M, 1.02 M, and 1.8 M sucrose (ultrapure; e.g., ICN Biochemicals) in dilution solution
Dilution solution: 50 mM Tris·Cl (pH 7.4)/25 mM KCl/5 mM $MgCl_2$
Ultraclear or polyallomer ultracentrifuge tubes to fit a swinging-bucket rotor (e.g., 38 ml for Beckman SW28 rotor or equivalent; 13 ml for SW41 rotor or equivalent; 5 ml for SW50.1 or SW55 rotor or equivalent)
Gradient-forming device (see Fig. 4.1.2)
Ultracentrifuge and swinging-bucket rotor (e.g., Beckman SW28, SW41, SW50.1, or SW55)
Syringe (with blunt needle), plastic transfer pipet, or siliconized glass Pasteur pipet

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after removing and weighing tissue should be conducted at 0°C (ice bucket) or 4°C (cold room).

Prepare sample by homogenization and low-speed centrifugation

1. Remove liver from a freshly sacrificed rat that has been fasted overnight (to deplete hepatic glycogen). Weigh liver, mince, homogenize, and filter through cheesecloth as for velocity centrifugation (see Basic Protocol 1, steps 1 to 3), except homogenize at 15% (w/v) in 0.25 M sucrose medium.
2. Add 1 vol of 1.8 M sucrose medium to the homogenate to give 1.02 M sucrose final.

Load and run gradients

3. Load the adjusted homogenate into centrifuge tubes to fill ≤½ the tube volume.

   It is important not to overload individual gradients with sample, as overloading promotes aggregation and decreases resolution and purity.

4. Use a gradient-forming device to form a continuous sucrose gradient on top of the loaded samples. To form the gradient, place 0.25 M sucrose solution in the back reservoir of the gradient-forming device and 1.02 M sucrose solution in the mixing chamber. Open the connecting channel and pump the gradient into the tube (high density first), making sure that the outlet remains above the level of the solution in the filling tube (see Fig. 4.1.2).

   Alternatively, the continuous gradients can be prepared in advance and kept at 4°C for a few hours before loading. In this case, use a syringe with a long needle to carefully load the 1.02 M–adjusted homogenate beneath the gradient in each tube.

5. After the gradients are made, insert the tubes into the buckets of the swinging-bucket rotor. Weigh buckets plus tops and balance in pairs by adding a small amount of the lowest-density sucrose medium to the lighter tube of each pair.
6. Centrifuge tubes 3 hr at 100,000 × *g* (e.g., 28,000 rpm in Beckman SW28), 4°C. Allow the rotor to coast to a stop with the brake off.

   If the deceleration is too rapid, the layers of sucrose (e.g., between the load zone and the gradient) rotate relative to one another, which causes vortexing into the overlying sucrose layer(s) and decreases the resolution. With older ultracentrifuges (Beckman L5-50, L5-65, and older), the rotor coasts to a stop from maximal speed, taking ~30 min from 28,000 rpm. As most of the disturbance of gradients occurs below the final 1000 rpm of deceleration, newer instruments decelerate to 800 rpm and then coast to

CU IASI CENTRAL UNIVERSITY LIBRARY

a stop, taking significantly less time. Run times are given for older instruments, and can be adjusted downward to accommodate the new deceleration pattern.

Unload the gradients and collect fractions

7. Carefully remove the gradients from the rotor buckets, place in a rack, and note the positions of the bands.

   For the example described here (starved rat liver), a prominent band was found to have floated ~⅓ of the way into the gradient (i.e., ~⅓ of the way up) while a second band was observed at the air/0.25 M sucrose interface.

8. Begin collecting the fractions (bands) separately starting from the top, using a syringe (with blunt needle), plastic transfer pipet, or siliconized glass Pasteur pipet. Be sure to collect thoroughly: first sweep the circumference of the tube with the syringe or pipet tip, then pass the tip systematically across the interface while applying suction.

   Because the direction of centrifugation is radial, bands are more highly concentrated at the walls of the tube than in the center (see UNIT 4.1 for discussion of rotor geometry).

9. If recovery of total activity of the loaded sample is a goal of the experiment, collect aliquots of the solution between bands, as well as aliquots of the original sample and the pellet (after resuspension), as separate samples for assay.

Process individual fractions

10. Dilute each band at least 2- to 3-fold with buffer or a low-concentration sucrose medium. Pellet by velocity sedimentation for ≥100,000 × *g* (e.g., 40,000 rpm in Beckman SW41 or SW50.1), 4°C, then resuspend in the same medium for further use.

    Process Golgi fraction by adding dilution solution to 0.25 M sucrose final (use a refractometer, if available, to measure the sucrose concentration), then pelleting 1½ hr at 100,000 × g, 4°C.

    Generally bands obtained by isopycnic centrifugation are not as concentrated as resuspended pellets obtained by differential velocity sedimentation (see Basic Protocol 1). Furthermore, individual bands are suspended in media with differing densities.

11. If desired, subfractionate the samples further—for example, by lysis to separate membranes from soluble content or by high pH (carbonate) treatment, which is frequently used to strip membranes of extrinsic proteins (see Basic Protocol 9).

    As an alternative to the continuous gradient procedure, it is also possible to generate Golgi fractions (and especially subfractions enriched in different Golgi cisternae) by flotation on a discontinuous sucrose gradient. In this case, the starting sample is a crude microsomal pellet (see Basic Protocol 1) that has been resuspended in 1.15 M sucrose/50 mM Tris·Cl (pH 7.4)/25 mM KCl/5 mM $MgCl_2$. Above this sample in the centrifuge tube are placed layers of 1.0 M, 0.86 M, 0.6 M, and 0.25 M sucrose solution, and the tubes are spun as above. Bands are then collected at each interface: the 0.25 M/0.6 M interface is the light Golgi fraction; the 0.6 M/0.86 M interface is the intermediate Golgi fraction; the 0.86 M/1.0 M interface is the heavy Golgi fraction; and the 1.0 M/1.15 M interface is the small vesicular fraction (Bergeron et al., 1982).

    Because the liver produces very low density lipoproteins that transiently accumulate in the Golgi before export to the cell surface, Golgi from this source has an unusually low buoyant density and is especially favorable for preparing reasonably purified fractions. Golgi fractions from other sources are more dense, and so far most preparations from nonhepatic sources are not as pure.

BOSTON UNIVERSITY LIBRARY

ALTERNATE PROTOCOL 1

RATE ZONAL CENTRIFUGATION USING SUCROSE

Rate zonal centrifugation is a nonequilibrium density gradient procedure for fractionating cells, in which sedimentation depends on the size, density, and shape of the particles as well as the viscosity and density of the medium. Typically, samples are loaded atop a continuous sucrose gradient; during subsequent reasonably short centrifugations (length of run and rate often need to be determined empirically), they separate as distinct bands (zones) enriched in particular organelles. This procedure can be adapted to various-sized gradients; available models of gradient-forming devices can be used to generate gradients in tubes ranging from 5 to 38 ml. To prepare gradients in smaller tubes (e.g., for a tabletop ultracentrifuge), investigators often approximate continuous gradients by preparing step gradients having several layers of progressively decreasing density, then letting them stand a few hours before use. Diffusion between the layers makes the approximation quite good.

The example described in this protocol is the separation of a postnuclear supernatant (PNS) from exocrine pancreas. It can be adapted to other tissues or cell cultures but this may require adjusting the density limits of the gradient. See, for example, the preparation of Golgi membranes for cell-free assays (Balch et al., 1984). Figure 4.2.1 presents the results of assaying marker activities of several organelles across the gradient. Ficoll 400 (a hydrophilic polymer; see *UNIT 4.1*) has been added to the sucrose to retard the migration of mitochondria relative to zymogen granules so that these two abundant organelles are resolved as distinct bands.

Materials

Rat starved overnight and freshly sacrificed
Homogenization medium: 0.3 M sucrose (ultrapure; e.g., ICN Biochemicals) plus 0.2 µg/ml diphenyl-*p*-phenylenediamine (DPPD, Kodak; from 0.4 mg/ml stock in ethanol)
1 M MES
0.2 M EDTA (*APPENDIX 2E*)
Gradient stock solutions, low- and high-density (see recipe)
0.3 M sucrose/5 mM MES/1 mM EDTA/0.2 µg/ml DPPD, pH 6.5 to 6.7

Cheesecloth
Dounce homogenizer
Gradient-forming device (see Fig. 4.1.2) suitable for selected gradient size, including compatible magnetic stir bars, tubing, and peristaltic pump
Ultraclear or polyallomer centrifuge tubes (of the selected size) suitable for swinging-bucket rotor
Plastic tissue culture pipet or polyethylene transfer pipet
Ultracentrifuge and appropriate swinging-bucket rotor (e.g., Beckman SW50.1 or SW55 if using 5-ml tubes; Beckman SW28 for 38-ml tubes)
Automated gradient-collection device (e.g., Buchler Autodensiflow, Nyegaard or MSE Scientific) *or* micropipettor for manual collection

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after removing and weighing tissue should be conducted at 0°C (ice bucket) or 4°C (cold room).

Prepare the pancreatic samples

1. Remove pancreas from freshly sacrificed rat that has been fasted overnight (to maximize the zymogen granule population). Weigh pancreas (usually 0.8 to 1 g per animal), mince, homogenize, and filter through cheesecloth (as for liver; see Basic

CU IASL CENTRAL UNIVERSITY LIBRARY

Protocol 1, steps 1 to 3), except use homogenization medium containing 0.2 μg/ml DPPD and homogenize at 15% (w/v).

DPPD, an antioxidant, is added because it significantly reduces lysis of zymogen granules.

2. Centrifuge sample, rehomogenize (in the same volume as initially used of homogenization medium containing DPPD), and recentrifuge, then pool supernatants (see Basic Protocol 1, steps 4 and 5). Add MES to 5 mM (from 1 M stock) and EDTA to 1 mM (from 0.2 M stock). Filter and disperse with a Dounce homogenizer (see Basic Protocol 1, step 5). Maintain homogenized sample (PNS) at 0°C, preferably briefly, until loaded on the gradients.

Prepare the continuous gradients

3. Set up the gradient-forming device and peristaltic pump as shown in Fig. 4.1.2.
4. Load the gradient-forming solutions. Into the back chamber (reservoir) of the gradient former, pipet the high-density sucrose solution (15 ml for 38-ml tubes; 5 ml for 12.5-ml tubes; 2.2 ml for 5-ml tubes). Carefully bleed a little of the solution through to the front (mixing) chamber to displace the air in the joining tube. Then pipet the low-density solution into the mixing chamber (same volumes as for high-density solution). Be sure that in this configuration that the delivery tube is at the bottom of the centrifuge tube, as the gradient will be generated low density first (see Fig. 4.1.2).
5. Start the stirring motor and the peristaltic pump, and immediately open the joining tube between the two chambers. Note the Schlieren patterns in the mixing chamber as high-density sucrose flows in, first as is, then mixed. Set the delivery rate of the peristaltic pump empirically; if it is too fast, the solution level in the mixing chamber will drop below that in the delivery chamber and mixing will appear incomplete.
6. Once delivery of the solutions from the gradient-forming device to the centrifuge tubes is complete, shut off the peristaltic pump before air in the emptying delivery tube reaches the gradient. Slowly withdraw the delivery tube up through the gradient so disturbance to the gradient is minimal.

Continuous gradients are quite stable and can be prepared the day before use provided they are stored at 4°C without disturbance.

Load the sample on the gradients and centrifuge

7. Using a plastic tissue culture pipet or polyethylene transfer pipet, carefully overlay the gradients with samples of PNS. Maximal volumes of the 7.5% (w/v) PNS that can be loaded without overloading and decreasing resolution are 5.5 ml on a 30-ml gradient, 1.8 ml on a 10-ml gradient, and 0.5 ml on a 4.5-ml gradient.

To the inexperienced investigator, use of pipets may sound tricky. In our experience, nice layering with little mixing can be achieved rather quickly by placing the tip of the pipet on the meniscus of the solution while slightly tilting the tube containing the partly layered gradient, then gradually relaxing the pressure on the finger controlling the flow from the pipet. Some practice may be necessary! As an alternative, polyethylene transfer pipets can be used to load the solutions.

8. Place the loaded gradients into the buckets of the appropriate swinging-bucket rotor, taking care that the tubes are not wet on the outside. Balance opposite buckets to within 0.1 g of each other using homogenization medium.

Generally, with accurate pipetting during forming and loading, only minor adjustment is required for balancing.

9. Centrifuge the samples in the ultracentrifuge set at 4°C. For rate zonal centrifugation,

BODLEIAN LIBRARY OXFORD UNIVERSITY

which is a nonequilibrium procedure, the angular velocity and length of the run may require empirical adjustment.

For pancreatic PNS centrifuged in an SW28 rotor, excellent separation conditions are obtained by spinning 110 min at 26,000 rpm (90,000 × g), 4°C, then letting the rotor coast to a stop without the brake.

10. At the end of the run, the gradients should show discrete bands or zones that are enriched in specific organelles; these zones are distributed throughout the gradient.

Collect the gradients at 4°C

11. Unload the gradients in successive fractions of equal volume using an automated collection device or a micropipettor. For large-volume gradients in 38-ml tubes, a Buchler Autodensiflow device, which collects from the top, works very well. For small-volume gradients, collection can be satisfactorily performed using a micropipettor, taking care to withdraw the solution slowly and from as close to the surface as possible.

12. Assay the gradient fractions for the activity of interest. For some assays it may be necessary to reduce the sucrose content and/or concentrate the sample. If so, dilute fractions 2- to 3-fold with 0.3 M sucrose/5 mM MES/1 mM EDTA/0.2 µg/ml DPPD and pellet 1 hr (or shorter if the volume is small) at 100,000 × *g*, 4°C.

Figure 4.2.1 shows the results obtained by assaying the gradient fractions obtained by rate zonal centrifugation of the pancreatic PNS for enzymes that mark particular organelles.

ALTERNATE PROTOCOL 2

GRADIENT FRACTIONATION USING PERCOLL

Percoll (polyvinylpyrrolidone-coated colloidal silica) is a useful alternative to high-concentration sucrose gradients, particularly where high densities combined with low viscosity and osmotic activity are desired. Cells are homogenized, mixed with a Percoll solution, and centrifuged, generally using a fixed-angle rotor. The Percoll forms its own density gradient during centrifugation (a self-forming gradient). As it has very low osmotic activity (pure Percoll as purchased is ~10 mOsm), it is generally added to isoosmotic (or slightly hyperosmotic) sucrose for separating organelles from cell homogenates under isoosmotic (or near isoosmotic) conditions. The density range is controlled by the Percoll concentration, and the slope of the density gradient is determined by the time of centrifugation and the centrifugal field (see Fig. 4.2.2). Generally, the duration of separation procedures is selected so that organelles sediment to near equilibrium density (isopycnic conditions). Short runs (~30 min) enable large particles such as 1-µm-diameter secretion granules and mitochondria to approach equilibrium, whereas longer runs (up to 2 hr) may be required for smaller particles.

In the example presented in this protocol, Percoll gradients are used to purify secretion granules from exocrine glandular tissue and then to separate the granules into subpopulations according to the extent of their maturity (see Zastrow and Castle, 1987). The initial purification procedure is widely applicable to other types of granules.

Additional Materials *(also see Alternate Protocol 1)*

Percoll gradient solutions (see recipe)
Centrifuge and fixed-angle rotor (e.g., Beckman 70Ti or Type 50)
Centrifuge tubes (e.g., Beckman thick-walled polycarbonate bottle assemblies; 25-ml for 70Ti rotor or 10-ml for Type 50 rotor)
Refractometer

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

CU IAS - CENTRAL UNIVERSITY LIBRARY

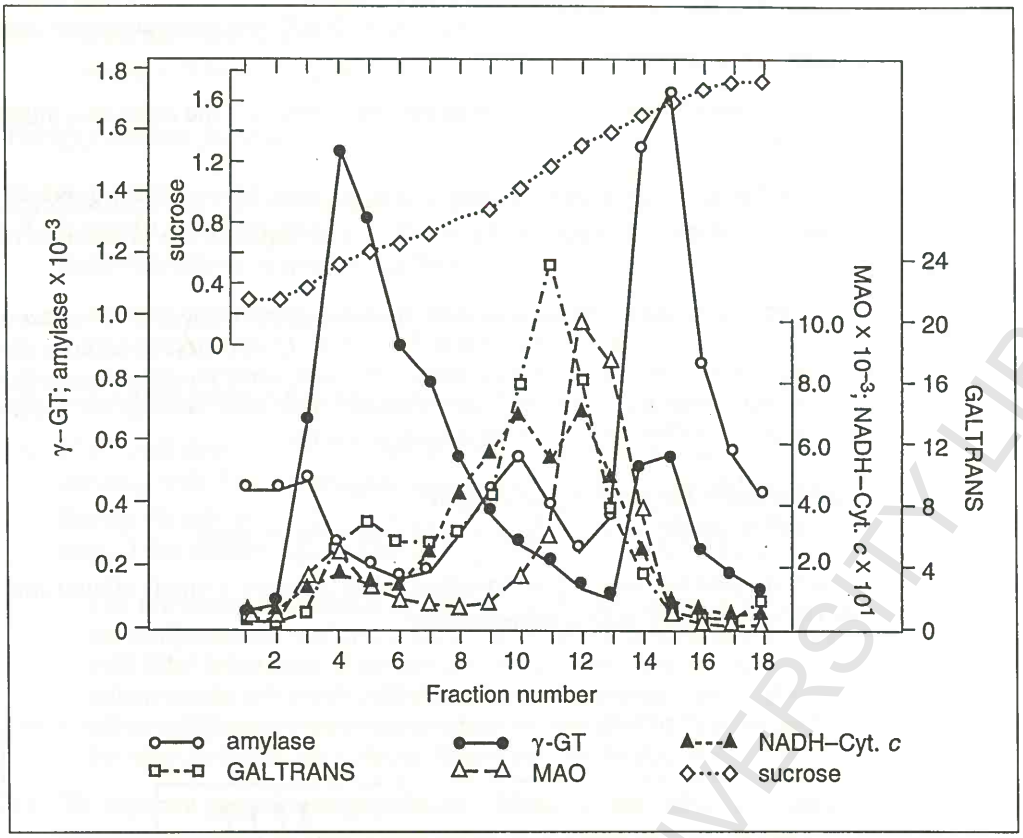

Figure 4.2.1 Distribution of marker activities for various organelles after rate zonal centrifugation of a postnuclear supernatant (PNS) from rat pancreas using the conditions specified in Basic Protocol 1. The density profile of the gradient after the run was determined by refractive index and plotted as sucrose (sucrose plus Ficoll) concentration; this is shown in the upper portion of the figure. The density profile of the gradient after the run was determined by refractive index and is shown in the upper portion of the figure. The activities that were assayed and the organelles that they mark are: amylase, a secretory protein concentrated in zymogen granules at the bottom of the gradient but also found in lower amounts in rough endoplasmic reticulum, Golgi, and at the top of the gradient (as a result of organelle lysis during homogenization); GALTRANS, galactosyltransferase, a marker for Golgi; γ-GT, gamma-glutamyl transferase, an integral component of plasma membrane but also of zymogen granule membranes (at lower concentration); MAO, monoamine oxidase, a marker of mitochondria (which is concentrated in outer mitochondrial membranes; also note the small amount near the top of the gradient resulting from organelle breakage); NADH–Cyt.*c*, NADH–cytochrome *c* reductase, a marker activity of rough ER and mitochondria. The distinct but overlapping distributions of these markers in this analytical centrifugation is apparent.

NOTE: All operations after removing and weighing tissue should be conducted at 0°C (ice bucket) or 4°C (cold room).

Load and spin the samples

1. Remove parotid salivary gland from freshly sacrificed rats (0.4 to 0.5 g tissue per animal). Weigh gland, mince, homogenize, and filter through cheesecloth (see Basic Protocol 1, steps 1 to 3), except using homogenization medium containing DPPD (as in Alternate Protocol 1) and homogenizing at 12% (w/v).

   DPPD, an antioxidant, is added because it significantly reduces lysis of zymogen granules.

2. Centrifuge sample, rehomogenize (in homogenization medium with DPPD), and recentrifuge, then pool supernatants (see Basic Protocol 1, steps 4 and 5). Add MES

BOSTON UNIVERSITY LIBRARY

to 5 mM and EDTA to 1 mM. Filter and disperse with a Dounce homogenizer (see Basic Protocol 1, step 5).

3. Add the PNS to 2 vol of 60% Percoll/sucrose and mix. Measure the refractive index using a refractometer.

4. Load into tubes that are appropriate for the fixed-angle rotor that has been selected. Centrifuge the samples under appropriate conditions to separate the organelles of interest.

   To separate parotid gland secretion granules, appropriate centrifugation conditions are 30 min at 16,400 × g (e.g., 15,000 rpm in 70Ti), 4°C. Under these conditions the granules separate as a white band at the bottom of the tube, while the other organelles form a dense band near the top of the tube. A mostly clear zone between the bands corresponds to the shallow portion of the density gradient.

Collect bands and prepare for further purification

5. Collect the bands manually using a Pasteur or plastic transfer pipet.

6. For each fraction, mix by swirling or inverting, then remove a small aliquot and measure its refractive index with a refractometer.

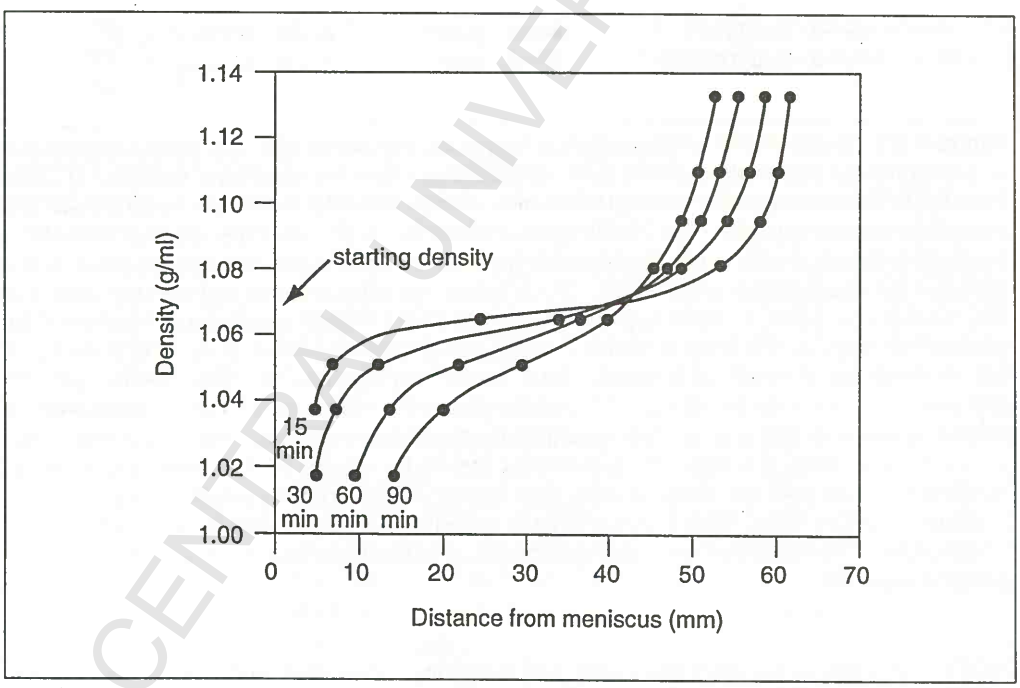

Figure 4.2.2 Percoll density gradient profiles as a function of time of centrifugation at 20,000 × *g* in a fixed-angle rotor. The starting density in the example shown is 1.07 g/ml. Note that with self-forming density gradients, the slope of the gradient begins as zero; during the run, the shape progressively changes as the Percoll sediments. Early in the run most of the tube contains a shallow gradient that is bordered by Percoll-depleted solution at the top and high-density pelleted Percoll at the bottom. As the run proceeds, the central resolving segment of the gradient becomes steeper and shorter. To produce an isoosmotic sucrose/Percoll solution of a desired density, use the formula:

$$\frac{V_x}{V_o} = \frac{\rho_o - \rho_x}{\rho_i - \rho_x}$$

where V_x = volume of 2.5 M sucrose, V_o = volume of Percoll, ρ_o = density of Percoll (1.13 g/ml), ρ_x = density of 2.5 M sucrose (1.315 g/ml), and ρ_i = desired density. Figure courtesy of Pharmacia Biotech.

CCU IASI CENTRAL UNIVERSITY LIBRARY

7. Adjust the refractive index back to the same value measured for the original diluted PNS by adding homogenization medium.

Purify fractions further

Example: For parotid-gland secretion granule fraction:

8. Load the adjusted granule fraction into centrifuge tubes and recentrifuge under the same conditions as used in the first run.

   This repeat centrifugation will float much of the residual contaminants away from the granule fraction.

9. Collect the granule fraction manually with a pipet.

10. If desired, process the purified granule fraction as a single organelle population by diluting with 3 vol homogenization medium, then pelleting the granules by centrifuging 45 min at 2000 × *g* (e.g., 5000 rpm in 70Ti), 4°C. Alternatively, proceed to step 11 for further separation of the granule fraction by Percoll centrifugation.

    The low-speed centrifugation removes most, but not all, of the Percoll and provides an easily resuspended pellet. Removal of Percoll is necessary because it can interfere with later processing of the sample. If necessary, further Percoll removal and purification can be achieved by dilution and recentrifugation under the same conditions, by ultracentrifugation on a step gradient as specified by Zastrow and Castle (1987), or by other methods (see Critical Parameters for further discussion).

11. To separate granule subpopulations: Measure the refractive index of the granule fraction collected in step 9 and adjust to a value of $n = 1.3586$ using either 0.3 M sucrose or 86% Percoll/sucrose, depending on whether refractive index must be adjusted downward or upward, respectively.

    The value of n will differ and must be determined empirically for granules from other sources.

12. Place the adjusted granule fraction in a new set of centrifuge tubes and centrifuge 30 min at 45,500 × *g* (e.g., 25,000 rpm in 70Ti or Type 50 rotor, depending on the volume), 4°C.

13. The granule fraction will now be subdivided into a minor upper band, a major lower band, and the clearer (but slightly turbid) zone between the bands. Collect the upper band, the intervening zone, and the lower band as separate fractions.

    Together these fractions comprise a continuum of increasingly dense granules (and increasing granule maturation), rather than discrete subpopulations. Evidently, the relative amounts of granules in each subfraction depend on the initial density (and thus refractive index) before the spin and on the centrifugation conditions (because Percoll gradients are self-forming and constantly change during the centrifugation).

15. Process the collected bands as in step 10 to remove Percoll. Proceed with analysis.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

ALTERNATE PROTOCOL 3

GRADIENT FRACTIONATION USING D_2O

Deuterium oxide fractionation takes advantage of the fact that the density of D_2O is 1.1 g/ml—substantially closer than that of water to the density of biological organelles. The procedure is a form of equilibrium centrifugation in which D_2O (heavy water) is substituted for H_2O. This technique has not been used widely in subcellular fractionation, largely because deuterium oxide is quite expensive, and also because the practical value of the approach has fallen short of expectations. In some cases, however, it can be quite effective, so it should be considered as an option.

The procedure presented below (taken from Gumbiner and Kelly, 1981) illustrates use of a combined Ficoll/D_2O density gradient to purify and analyze endocrine secretion granules derived from a pituitary cell line.

Additional Materials (also see Alternate Protocol 1)

Mouse pituitary AtT-20/D16V cells
PBS (*APPENDIX 2E*) containing 4 mM EGTA (from 100 mM EGTA, pH 7.4), 37°C
Homogenization medium: 0.25 M sucrose (ultrapure; e.g., ICN Biochemicals)/10 mM HEPES (pH 7.4)/2 mM EGTA/1 mM EDTA, 4°C
Deuterium gradient stock solutions: 0.25 M ultrapure sucrose/10 mM HEPES (pH 7.4)/1 mM EDTA in D_2O (e.g., Aldrich), with and without 20% (w/v) Ficoll
8% (w/v) Ficoll 70 (Pharmacia Biotech) in homogenization medium

75-cm^2 tissue culture flasks
Dounce glass homogenizer with type B pestle (Kontes or equivalent)
Sorvall centrifuge and SS-34 rotor (or equivalent)
Gradient-forming device with capacity ≥15 ml/chamber (Hoefer Pharmacia or equivalent)
Peristaltic pump to form continuous gradient
Ultracentrifuge with swinging-bucket rotor (e.g., Beckman SW27 or SW28)
Automated gradient collection apparatus: Autodensiflow device (Buchler) or gradient displacement device (Nyegaard or MSE Scientific)

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after harvesting cells should be conducted at 0°C (ice bucket) or 4°C (cold room).

Homogenize the cells and prepare the crude granule pellet

1. Grow cells almost to confluency in five 75-cm^2 tissue culture flasks (~5×10^6/flask). Harvest cells at 37°C in PBS/4 mM EGTA and pellet at 4°C.
2. Resuspend in 15 ml of 4°C homogenization medium and homogenize with six strokes in a Dounce homogenizer.

   A newer ball-bearing homogenizer designed by Balch and Rothman (1985) is now used widely for homogenizing cultured cells.

3. Pellet large debris and organelles by centrifuging 5 min at 10,000 × *g* (e.g., 9500 rpm in SS-34 rotor in a Sorvall centrifuge), 4°C.
4. Transfer the supernatant to a fresh tube and centrifuge 35 min at 30,000 × *g* (16,000 rpm), 4°C, to pellet the crude granule fraction.
5. Resuspend the crude granule pellet in 1 to 2 ml homogenization medium using a micropipettor until fine particulates are no longer seen. If necessary, homogenize

CU IASI CENTRAL UNIVERSITY LIBRARY

using a small-capacity Dounce homogenizer to achieve the desired uniform suspension. Maintain on ice while preparing the gradient.

Prepare the Ficoll-D_2O gradient

6. Using the gradient stock solutions made in D_2O (with and without 20% Ficoll), prepare layering solutions that are 17%, 14%, 11%, 9%, and 8% Ficoll.

7. Prepare a Ficoll step gradient (in 100% D_2O) at the bottom of each tube by layering the following solutions (from step 6) using either a micropipettor or plastic tissue culture pipet:

   1 ml 20% Ficoll
   2 ml 17% Ficoll
   2 ml 14% Ficoll
   2 ml 11% Ficoll
   1 ml 9% Ficoll.

   The volumes specified are for a 38-ml centrifuge tube, which is used in an SW27 or SW28 rotor.

8. Mix 8 ml of 20% Ficoll gradient stock solution with 12 ml homogenization medium to give 20 ml of 8% Ficoll in 40% D_2O medium.

9. Place 14.5 ml of the 8% Ficoll/40% D_2O solution in the back reservoir of a gradient-forming device. After filling the delivery tube between the chambers, place 14.5 ml of the 8% Ficoll in 100% D_2O gradient stock solution (from step 6) into the mixing chamber. Open the delivery tube, starting stirring the mixing chamber, and start the peristaltic pump to deliver a continuous gradient 40% to 100% D_2O in 8% Ficoll on top of the Ficoll step gradient.

Load the sample and spin

10. Load the resuspended crude pellet on the gradient and centrifuge 12 to 15 hr at 82,500 × *g* (e.g., 26,000 rpm in SW27 or SW28 rotor), 4°C.

    The centrifugation conditions listed (including tube size and rotor) are those reported by Gumbiner and Kelly (1981). It is very likely that this procedure can be successfully scaled down for use with smaller samples and smaller-volume gradients.

Collect fractions from the gradient and analyze

11. Collect 1.5-ml gradient fractions using one of the following methods:

    a. Collect top-first manually using a micropipettor.

    b. Collect top-first by an automated method: use either a Buchler Autodensiflow device or gradient displacement device (e.g., Nyegaard or MSE Scientific).

    c. Collect bottom-first by puncturing a hole in the bottom of the tube and collecting drops.

    The third method was used in the published procedure (Gumbiner and Kelly, 1981).

    Analyses for the secretion granule marker ACTH and total protein indicate that granules are highly purified, 50-fold on average, and are located within the lower Ficoll gradient/100% D_2O portion of the tube (centered at a density of 1.17 g/ml). Most other organelles are centered within the 8% Ficoll/D_2O gradient portion of the tube as judged by the concentration of protein in this region. Soluble protein remains at the top of the gradient.

    Lysosomes are a problematic contaminant of endocrine secretion granules (e.g., Roep et al., 1990; Loh et al., 1984) and have not been assayed specifically in this procedure.

BOSTON UNIVERSITY LIBRARY

ALTERNATE PROTOCOL 4

GRADIENT FRACTIONATION USING NONIONIC IODINATED SOLUTES

Another strategy that is being used to achieve higher-density fractionation media with reduced osmolarity and viscosity involves supplementing or replacing sucrose with iodinated solutes. By far the most successful of these solutes are the nonionic derivatives of triiodobenzoic acid, metrizamide and Nycodenz (both available from Nyegaard). Metrizamide [2-(3-acetamido)-5-*N*-methylacetamido-2,4,6-triiodo(benzamido)-2-deoxy-D-glucose] and Nycodenz (*N,N'*-bis(2,3-dihydroxypropyl)-5-*N*-(2,3-dihydroxypropyl)acetamido-2,4,6-triiodoisophthalamide) are soluble in all aqueous media, stable over the pH range 2 to 12.5 and, unlike related ionic solutes, are not affected by low pH or the presence of divalent cations. These media are advantageous for fractionation under sterile conditions (Nycodenz can be autoclaved, whereas metrizamide must be sterile filtered). The differences in fractionation between these two media are negligible, and for most purposes, they are interchangeable. Note, however, that reported buoyant densities of selected organelles can differ slightly between the two (e.g., mitochondria has a density of 1.115 g/ml in metrizamide and 1.132 in Nycodenz). For a more extensive discussion of the properties of these solutes, see the monograph on centrifugation edited by Rickwood (1984).

This procedure describes purification of lysosomes from rat liver using a metrizamide gradient (Wattiaux et al., 1978); studies isolating other organelles by this method are noted in Background Information. In addition to preparing a high-quality fraction, these investigators show how results obtained with a continuous gradient are used to devise a step-gradient procedure for routine preparations.

Additional Materials (also see Alternate Protocol 1)

Rat starved overnight and freshly sacrificed
Homogenization medium: 0.25 M sucrose (ultrapure; e.g., ICN Biochemicals), 4°C
85.6% metrizamide (from 100% stock, Nyegaard)
Gradient stock solutions: for continuous gradients, 19.7% and 50% (w/v) metrizamide, pH 7.4; for step gradients, 19.78%, 24.53%, 26.34%, and 32.82% (w/v) metrizamide, pH 7.4 (adjust pH with 0.01 N NaOH)
Teflon-glass homogenizer (type C, 40 ml, A.H. Thomas)
Fixed-angle ultracentrifuge rotor appropriate to the size of the experiment (e.g., Beckman 70Ti)
Automated gradient collection apparatus: Autodensiflow device (Buchler) or gradient displacement device (Nyegaard or MSE Scientific)

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after removing and weighing tissue should be conducted at 0°C (ice bucket) or 4°C (cold room).

Prepare sample by homogenization and low-speed centrifugation

1. Remove liver from a freshly sacrificed rat that has been fasted overnight (to deplete glycogen stores). Weigh the liver, mince, and homogenize as for velocity centrifugation (see Basic Protocol 1, steps 1 to 2), except homogenize at ~20% (w/v) using a Teflon-glass homogenizer at 3000 rpm in 4°C homogenization medium (0.25 M sucrose).
2. Adjust the homogenate to 15% (w/v), then filter through cheesecloth. Centrifuge 15 min at 2,000 × *g*, 4°C.
3. Save the supernatant on ice and resuspend the pellet, adding homogenization medium

CU IAS / CENTRAL UNIVERSITY LIBRARY

to the original homogenate volume. Rehomogenize, then centrifuge again as in step 2.

4. Pool the two supernatants and centrifuge 30 min at 8,800 × *g* in a fixed-angle rotor (e.g., 10,000 rpm in 70Ti). Remove the supernatant, including the fluffy layer atop the pellet; resuspend the pellet in homogenization medium and repeat the centrifugation.

5. Resuspend the pellet in homogenization medium and mix with 2 vol of 85.6% metrizamide (to give a final 56.7% metrizamide load for the gradients).

Metrizamide and Nycodenz both absorb strongly in the UV range, complicating protein determinations in gradient fractions by OD_{280}. Also, they interfere with some protein assays (e.g., Lowry). To assay protein in various fractions, the samples can be precipitated with trichloroacetic acid and redissolved in 0.5 N NaOH. Metrizamide inhibits galactosyltransferase activity, so if this Golgi assay is to be performed, the fractions must be diluted, pelleted, and resuspended in a sucrose (or other noninhibitory) medium.

Prepare continuous metrizamide gradient and load sample

6. Using the gradient-forming device (Fig. 4.1.2), place the 50% metrizamide solution (density 1.280 g/ml) in the back reservoir and fill the delivery tube to the mixing chamber. Next place the 19.8% metrizamide solution (density 1.105 g/ml) in the mixing chamber. Set the outlet tube at the bottom of the centrifuge tube.

7. Open the delivery tube between the two chambers, start stirring in the mixing chamber, and pump the gradient (in low-density-first configuration).

Wattiaux et al. (1978) treats the continuous gradient as an analytical run and uses 5-ml gradients.

8. After the gradient is delivered, shut off the pump, taking care not to let air pass into the gradient from the outlet tube. Slowly withdraw the outlet tube from the centrifuge, taking care not to disturb the gradient.

9. Layer the sample in 56.7% metrizamide (final) beneath the gradient using either a Pasteur pipet or a syringe with long needle.

The reason for loading the gradient at the bottom is that mitochondria exhibit a higher equilibrium density when initially equilibrated in high-density metrizamide than when equilibrated in sucrose homogenization medium. This strategy is critical to achieving separation of mitochondria and lysosomes in the gradient.

10. Centrifuge the gradients 2½ hr at 108,000 × *g* (e.g., 28,000 rpm in SW28), 4°C.

Unload the gradients, measure refractive index, and assay marker activities

11. Working at 4°C, collect gradient fractions of equal volume using one of the following methods:

    a. Collect top-first manually using a micropipettor.
    b. Collect top-first by an automated method: use either a Buchler Autodensiflow device or gradient displacement device.
    c. Collect bottom-first by puncturing a hole in the bottom of the tube and collecting drops.

12. Measure the refractive index of each fraction. Using either a published table (available from Nyegaard) or standard curve constructed from a set of precisely made metrizamide stocks, construct a density profile for the gradient.

13. Using each gradient fraction plus an aliquot of the original gradient load, assay marker

BOYLAS / CENTRAL WINDSOR UNIVERSITY LIBRARY

activities for lysosomes (e.g., acid phosphatase, β-galactosidase), mitochondria (e.g., cytochrome oxidase), peroxisomes (e.g., catalase), and other organelles as desired.

14. From the activities present in each fraction, calculate the total recoveries of each of the enzymes present in the original gradient load. Plot the frequency of the components for each fraction as activity/(sum of the product of total enzyme activity × the density increment for each fraction).

Using these plots, it was found that peroxisomes equilibrate near the bottom of the gradient (median density 1.225 g/ml) with a portion of the catalase remaining in the load; mitochondria equilibrate near the middle (median density 1.162 g/ml); and lysosomes equilibrate in the upper region of the gradient (median density 1.133 g/ml).

Use step gradient to isolate specific organelles

Example: Isolate preparative levels of lysosomes

15. Based on the findings made using the continuous analytical metrizamide gradient (step 14), design an appropriate bottom-loaded step gradient. Resuspend the starting sample (light mitochondrial pellet) in homogenization medium, using 1 ml per 3 g original weight of liver, and mix with 2 vol of 85.6% (w/v) metrizamide (to give 56.7% load). Pipet 10 ml into a Beckman SW27 or SW28 tube, then overlay successively with 6 ml of 32.82% metrizamide (density 1.181 g/ml), 6 ml of 26.34% metrizamide (density 1.145 g/ml), 6 ml of 24.53% metrizamide (density 1.135 g/ml), and 9 ml of 19.78% metrizamide (density 1.109).

16. Centrifuge step gradient 2 hr at 95,000 × *g* (e.g., 27,000 rpm in SW27 or SW28), 4°C.

17. Collect bulk fractions from the top of the gradient using a pipet. Fraction 1 extends from the top to about two-thirds of the way through the 19.78% metrizamide layer; fraction 2 includes the 19.78%/24.53% interface (expected from step 14 to be enriched for lysosomes); fraction 3 includes the 24.53%/26.34% interface (expected from step 14 to be enriched for mitochondria); and fraction 4 includes the 32.82%/56.7% (load) interface (expected from step 14 to be enriched for peroxisomes).

18. Assay for marker activities and by electron microscopy to confirm that the fractions are enriched as expected.

Notably, Wattiaux et al. (1978) report that fraction 2 contained 10% to 12% of the lysosomal hydrolase activity of the total homogenate (a respectable yield) and had a specific activity for the lysosomal markers that on average was 74-fold higher than that of the homogenate (a very impressive purification).

BASIC PROTOCOL 3

GEL FILTRATION TO ISOLATE SECRETORY VESICLES

Gel filtration has not been applied widely in organelle purification; however, for small, homogeneous vesicles that can be included in the matrices of selected inert resins, it has proven to be valuable. As an example of this technique, the following protocol describes the use of Sephacryl S-1000 to fractionate the equivalent of a microsomal pellet obtained from a secretory vesicle–accumulating *sec6* mutant of *S. cerevisiae* (based on Walworth and Novick, 1987).

NOTE: During the first run of the column, substantial loss of material may occur, as there appears to be adsorption of lipid-rich vesicles to the column matrix. Adsorption can be substantially reduced by initially running sonicated phospholipid vesicles as a sample (this is also recommended when using controlled-pore glass). Alternatively, glyceryl CPG glass beads, which have a hydrophilic coating (polyethylene glycol or a similar polymer) that reduces surface adsorption, may be used.

CCU IASI CENTRAL UNIVERSITY LIBRARY

Materials

Saccharomyces cerevisiae sec6-mutant strain spheroplasted in 1.4 M sorbitol
Running buffer: 0.8 M sorbitol/10 mM triethanolamine/1 mM EDTA (pH 7.2; adjust pH with acetic acid)
1.5 × 90–cm to 1.5 × 100–cm column packed with Sephacryl S-1000 superfine resin (Pharmacia Biotech) and equilibrated with running buffer at 4°C

1-ml-capacity Dounce homogenizer
Centrifuges: low-speed and ultracentrifuge
Peristaltic pump capable of producing flow rates of ~10 ml/hr
Fraction collector

Additional reagents and equipment for gel-filtration chromatography (*UNIT 8.3*)

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after harvesting cells should be conducted at 0°C (ice bucket) or 4°C (cold room).

Load and run the column

1. Lyse spheroplasted yeast in running buffer using a Dounce homogenizer.

   Conditions for spheroplasting can be found in Becker and Lundblad (1994). The running buffer is made with sorbitol instead of sucrose because yeast metabolize sucrose.

2. Centrifuge the lysate 10 min at 10,000 × *g*, 4°C, to remove mitochondria and larger particulates.
3. Remove the supernatant and centrifuge 1 hr at 100,000 × *g*, 4°C, to produce a microsomal pellet.
4. Resuspend the pellet in 600 µl running buffer and disperse using a Dounce homogenizer.
5. Remove running buffer from above the resin bed of the column and load the sample at 4°C.

   The column size suggested is suitable for most applications; a smaller-dimension column has been used by Barlowe et al. (1994) in fractionating small amounts of radiolabeled material.

   Additional information on column packing and setup may be found in UNIT 8.3.

6. Once the sample has entered the resin bed, overlay the bed with running buffer and, using a peristaltic pump, elute the column at a flow rate of ~10 ml/hr, collecting fractions continuously.

   80-drop (4-ml) fractions were collected by the investigators who designed this procedure.

Assay the column fractions and process those of interest

7. Vesicles small enough to enter the pores of the resin at least partially run in the included volume of the column; larger vesicles are excluded and appear in the void volume; and soluble proteins elute mostly after the vesicles. Locate the vesicle of interest in the column profile by assaying for a marker activity.

   A sample elution profile (Walworth and Novick, 1987) is shown in Figure 4.2.3.

   Invertase is used as a marker in the case of secretory vesicles (biosynthetically labeled secretory protein could also be used, as in Barlowe et al., 1994).

8. Pool the peak fractions and concentrate the vesicles for further study by centrifuging 1 hr at 100,000 × *g*, 4°C.

BCU IMS / CENTRAL UNIVERSITY LIBRARY

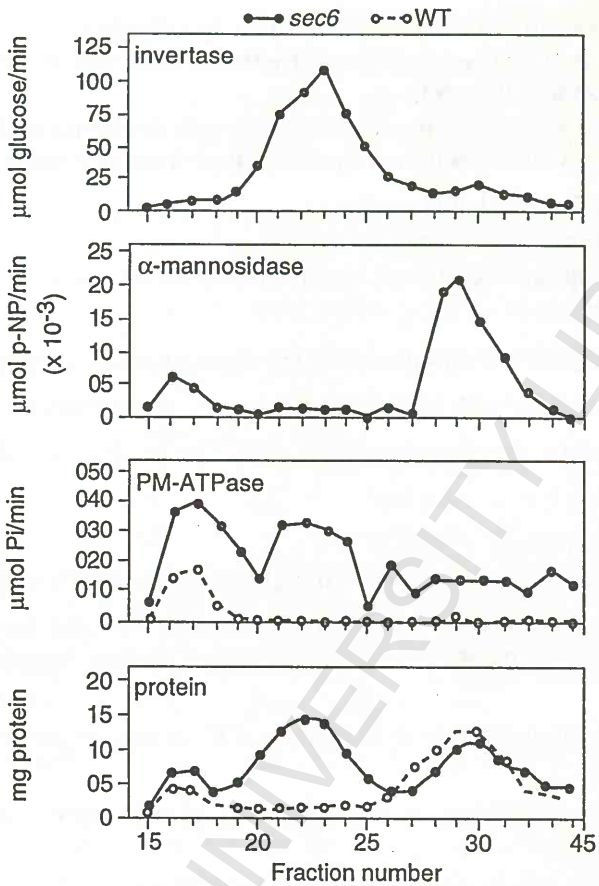

Figure 4.2.3 Distribution of organelle marker activities across eluted fractions from a Sephacryl S-1000 column on which a resuspended microsomal pellet from *sec 6-4* mutant (or wild-type) yeast was loaded. Fractions were assayed for invertase (a secretory protein), α-mannosidase (a vacuolar marker), plasma membrane ATPase, and protein. Invertase marks the distribution of secretory vesicles that accumulate in the *sec 6-4* mutant (but are absent in wild-type yeast). Part of the plasma membrane ATPase, but <1% of α-mannosidase, codistributes with invertase-containing secretory vesicles in the mutant. The protein indicates that significant protein elutes at the position of the vesicle peak for microsomes derived for mutant but not wild-type yeast. Reproduced from Walworth and Novick (1987) with permission of The Rockefeller University Press.

BASIC PROTOCOL 4

PREPARATIVE ELECTROPHORETIC SEPARATION

Electrophoretic purification can be used to separate complex mixtures of small vesicles that differ only modestly in size and density, because it takes advantage of the differences in their surface charges. This technique can be used preparatively or (as is more common) at the analytical level (Alternate Protocol 5), to separate and analyze organelles that have been selectively labeled. In this protocol, agarose electrophoresis using material derived from rat liver (Kedersha and Rome, 1986) is presented as an example of a preparative electrophoresis procedure. Although the protocol presented here used buffers of pH 6.5, the authors state that other pHs can be used, with resulting changes in the relative migration of different vesicles (as determined empirically).

Materials

Homogenization medium: 0.25 M sucrose (ultrapure; e.g., ICN Biochemicals)/50 mM 4-morpholinoethanesulfonic acid (MES), pH 6.5

ECU IAS/CENTRAL UNIVERSITY LIBRARY

6.25% sucrose/6.25% Ficoll 70/50 mM MES, pH 6.5
50 mM MES, pH 6.5
Running buffer: 50 mM MES (pH 6.5) with added sucrose as desired
0.15% to 0.2% Isogel agarose (FMC), or equivalent, in running buffer

Centrifuges: low-speed and ultracentrifuge
Standard flatbed agarose gel electrophoresis apparatus with 0.06-in. holes drilled in the cover to allow passage of inlet and outlet tubing from sample collecting wells (construct or purchase from Idea Scientific)
Standard 1.5-mm-thick plastic (siliconized) or Teflon gel comb
1.5-mm-thick plastic (siliconized) or Teflon eluting combs cut so that teeth are 3 mm wider than loading wells
0.062-in.-o.d. (1.57-mm) polyethylene tubing (Clay-Adams PE-160)
Peristaltic pump capable of flow rates of 0.2 to 15.0 ml/hr
Fraction collector

Additional reagents and equipment for preparing microsomal fractions (see Basic Protocol 1)

Prepare crude microsomal fraction

1. Prepare a crude rat liver microsomal fraction according to the procedure for differential centrifugation by velocity (see Basic Protocol 1), except using homogenization medium containing 50 mM MES. At the last step (see Basic Protocol 1, step 13), resuspend the crude microsome pellet in 6.25% sucrose/6.25% Ficoll 70/50 mM MES using a Dounce homogenizer.

2. Centrifuge the homogenate 40 min at 40,000 × *g*, 4°C, to pellet larger membrane vesicles.

3. Dilute the resulting supernatant with 4 vol of 50 mM MES or homogenization medium and centrifuge 2 hr at 100,000 × *g*, 4°C.

   Use homogenization medium (containing 0.25 M sucrose) in steps 3 and 4 if possible osmotic damage is a concern.

4. Resuspend the pellet (concentrated microsomes) in ≤0.8 ml of 50 mM MES (pH 6.5) or homogenization medium, and microcentrifuge 3 min at top speed to remove aggregates. Save the sample on ice until it can be applied to the gel (step 9).

   Samples for preparative electrophoresis can contain as much as 40 to 80 mg/ml protein.

Prepare and load the gel

5. Melt 0.2% Isogel agarose in running buffer using a microwave oven.

   FMC Isogel agarose is preferred because it has a low content of charged groups; it is usually used at concentrations of 0.15% to 0.2% but may be applied to separation of larger organelles (>200 nm diameter) when used at lower concentrations (<0.15%).

6. Cast the gel, with both the sample loading and eluting combs carefully prepositioned, and allow to solidify ≥2 hr at 4°C.

   Eluting combs are used to facilitate recovery of any particles that have diffused laterally (perpendicular to the field) during electrophoresis. Siliconization of plastic combs is recommended to minimize tearing of low-percentage agarose gels.

7. Remove eluting comb and immediately fill the eluting well(s) with running buffer. Keep the sample comb in place until just before loading.

BOUVIER CENTRAL UNIVERSITY LIBRARY

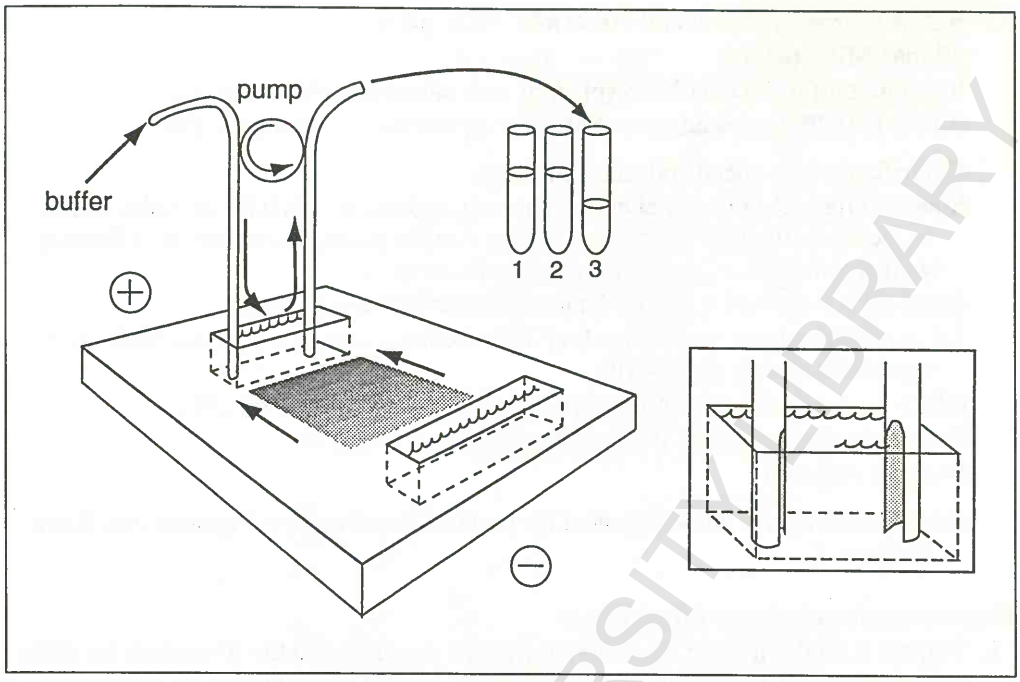

Figure 4.2.4 Schematic showing the horizontal agarose gel system devised by Rome and colleagues. Note the loading well, near (–) electrode, and the eluting well with continuous flow, near (+) electrode. The inset at the lower left shows the configuration of inlet and outlet tubing in the eluting well; note the cutouts from the walls of the tubing within the well. Figure courtesy of L. Rome with permission of Analytical Biochemistry.

8. Place the gel in the apparatus, taking care to align the elution wells with the holes in the lid.

   Electrophoresis is performed at 4°C, so all further operations should be conducted at this temperature (in a cold box or cold room).

9. Remove sample comb and load sample (from step 4).

10. Fill buffer reservoirs with running buffer until just level with the upper surface of the gel.

11. Attach the lid of the apparatus. Connect two pieces of 0.062-in.-o.d. polyethylene tubing whose ends have been cut away on one side to a peristaltic pump. Insert tubing through the holes in the lid and fully into the eluting well (see Fig. 4.2.4).

    The tubing provides buffer inlet and sample collection from the eluting well(s). The cutaway sides on the ends of the tubing should face one another for efficient buffer delivery and sample collection.

Run the gel and continuously collect the eluted fractions

12. Connect the electrodes, with the direction of electrophoresis running toward the (+) electrode (see Fig. 4.2.4), and turn on the power supply and the peristaltic pump. Set the current at 35 mA (~40 V). Adjust the flow rate on the peristaltic pump empirically.

    For example, for a 2-cm-wide elution well set 4 cm downfield from the sample well in a 1-cm-thick gel and an electric field of 1 V/cm, a flow rate of 4 ml/hr is reported to give quantitative elution.

13. Place a flask of warm water on the apparatus during the run to prevent condensation on the underside of the lid.

CU IAS / CENTRAL UNIVERSITY LIBRARY

14. Carry out the electrophoresis for 16 hr.

15. Collect 3 to 4 ml fractions (generally, 30 to 45 total fractions) and assay initially by analytical SDS-PAGE (*UNIT 10.1*) or by more specific assays for selected markers (e.g., dot blotting with an antibody).

    The duration of electrophoresis and the size of fractions collected will generally have to be adjusted empirically to suit the particular fractionation being performed.

15. Concentrate pooled fractions by centrifuging 30 min at 100,000 × *g*, 4°C. Resuspend the pellets in an appropriate buffer for further analysis.

ELECTROPHORETIC SEPARATION ON A DENSITY GRADIENT

ALTERNATE PROTOCOL 5

As indicated in the initial discussion of electrophoretic separations above (see Basic Protocol 4), electrophoresis has proven to be very useful for separating specific membrane populations from among similar-sized vesicles where there are unique surface charge characteristics. In this protocol, the unusually high negative surface charge on endosomes has enabled the identification of a novel population that accumulates MHC class II molecules en route to the cell surface. Its distribution following electrophoresis differs from the distributions of markers of other organelles but corresponds to the distributions of invariant chain processing and antigenic peptide loading (Tulp et al., 1994).

Additional Materials (also see Basic Protocol 4)

Rat starved overnight and freshly sacrificed
Electrophoresis buffer: 0.25 M sucrose (ultrapure; e.g., ICN Biochemicals)/10 mM triethanolamine/10 mM acetic acid/1 mM EDTA, pH 7.4
Trypsin, TPCK-treated (Worthington Biochemical or equivalent)
Soybean trypsin inhibitor
10%, 6%, 5%, and 4% (w/v) Ficoll 70, prepared in electrophoresis buffer

Electrophoresis apparatus: cylindrical electrophoresis chamber with dimensions of 5 cm high and 2.2 cm i.d. with circular palladium and platinum electrodes and cation-permeable membrane (Ionics, Inc.; see Tulp et al., 1993) *or* Polyprep 2000 apparatus (Buchler)
Gradient-forming device capable of forming linear concentration gradients of 10 ml volume (Hoefer Pharmacia)
1-mm-gauge stainless steel mesh

Additional reagents and equipment for preparing microsomal fractions (see Basic Protocol 1)

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after removing and weighing tissue, including forming and running the gradient, should be conducted at 4°C.

Prepare crude microsomal fraction

1. Remove liver from freshly sacrificed rat that has been fasted overnight (to deplete hepatic glycogen). Weigh, mince, homogenize, filter, and centrifuge at low speed as for centrifugation by differential velocity (see Basic Protocol 1, steps 1 to 4), using electrophoresis buffer as the homogenization medium and centrifuging 15 min at 840 × *g* to remove nuclei and larger debris.

2. Recover the supernatant (PNS), assay its protein content, and add trypsin (25 µg/mg PNS protein). Incubate 5 min at 37°C.

   Trypsin treatment is employed by most investigators who use electrophoresis to

BROWN UNIVERSITY LIBRARY

fractionate cellular organelles by electrophoresis. Treatment with trypsin enables compartments of the endocytic pathway to be resolved from other microsomal constituents (Marsh et al., 1987).

3. Stop the digestion by adding soybean trypsin inhibitor (100 µg/mg protein) and cooling on ice. Centrifuge 60 min at 100,000 × *g*, 4°C.

4. Resuspend pellet (crude microsomal fraction) in 0.5 ml of 5% Ficoll 70. Maintain on ice until it can be loaded for electrophoresis (step 7).

Set up the electrophoresis apparatus and load with the gradients and sample

5. Fill electrophoresis chamber with 10% Ficoll 70 via the inlet at the bottom. Fill the lower buffer reservoir with electrophoresis buffer.

A schematic diagram of an apparatus for electrophoretic separation is shown in Figure 4.2.5.

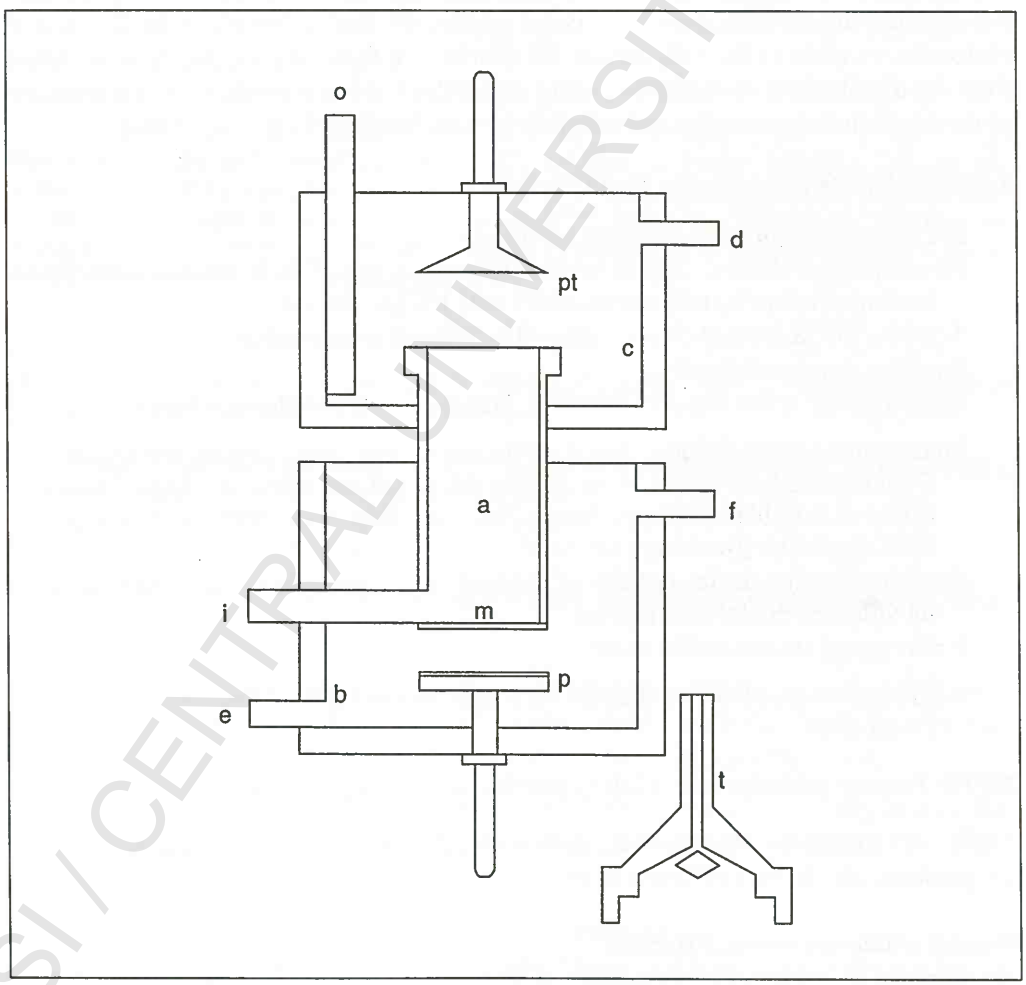

Figure 4.2.5 Apparatus used for electrophoresis on a density gradient. **a**, separation column (5 cm tall; 2.2 cm wide) containing the density gradient; **b**, bottom reservoir; **c**, top reservoir; **d**, outlet for the top reservoir; **e**, inlet for the bottom reservoir; **f**, outlet for the bottom reservoir; **i**, inlet for the separation column; **m**, cation-permeable membrane (part 61 AZL-386, Ionics Inc., MA, USA), which is held in place by a threaded fixture; **o**, inlet for the upper reservoir; **p**, circular (3.8-cm^2) palladium anode; **pt**, platinum cathode (3.8 cm^2); **t**, top cone with flow deflector (the inlet through which the Ficoll gradients are delivered). After removing **t**, the 1-mm-mesh stainless steel screen is placed atop **a** while the upper reservoir is filled, and the removed. After removing the screen, **pt** is installed and the electrophoretic separation is started. Reproduced from Tulp et al., 1993, with permission of VCH Verlagsgesellschaft.

ICU IASI / CENTRAL UNIVERSITY LIBRARY

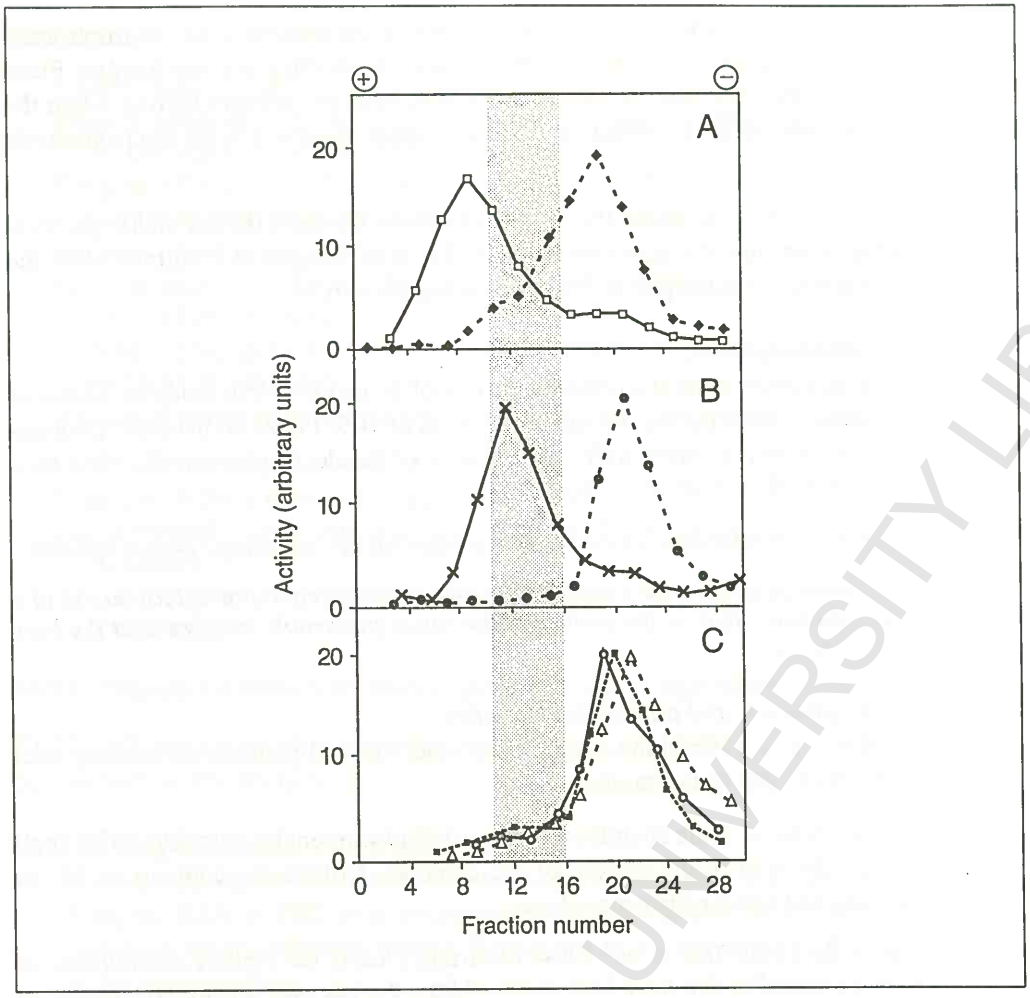

Figure 4.2.6 Results from density gradient electrophoresis of various organelles derived from cultured melanoma cells. (**A**) Distribution of horseradish peroxidase (HRPO) after endocytosis at 37°C. Filled diamonds show distribution of early endosomes (4 min HRPO uptake) and open squares show distribution of late endosomes (4 min HRPO uptake followed by 30 min chase at 37°C). (**B**) Distribution of the lysosomal hydrolase β-hexosaminidase (×) and plasma membranes that were marked in intact cells by surface iodination at 4°C using lactoperoxidase (filled circles). (**C**) Distributions of Golgi membranes (galactosyltransferase activity; open circles); ER (biosynthetically labeled by a 2-min pulse with ^{35}S methionine/cysteine; filled squares), and total protein (open triangles). The shaded region indicates where the bulk of a novel compartment containing MHC class II molecules are concentrated. Data are from Tulp et al. (1994); reprinted with permission from *Nature* (copyright 1994 Macmillan Magazines Ltd.).

6. Attach the gradient maker to the top inlet of the chamber and introduce a gradient (total volume 6 ml) descending from 10% to 6% Ficoll 70 above the 10% Ficoll. The gradient is formed and introduced into the electrophoresis chamber by displacement of the 10% Ficoll solution, which is allowed to drip slowly out of the lower inlet.

7. Load the crude microsomal sample (from step 4) above the Ficoll gradient, again by displacement of the 10% Ficoll solution, which is allowed to drip out of the lower inlet of the electrophoresis chamber.

8. Above the loaded sample, form and load a 9.5-ml continuous gradient of 4% to 0% Ficoll 70 by displacement of the 10% Ficoll at the bottom of the chamber. Upon completion, remove the loading inlet from above the electrophoresis chamber.

BODLEIAN LIBRARY UNIVERSITY

9. Allow 10% Ficoll 70 solution to drip from the inlet at the bottom of the electrophoresis chamber until the meniscus is level with the top of the electrophoresis chamber. Place 1-mm-gauge stainless steel screen over the meniscus (to prevent mixing when the upper reservoir buffer is added) and fill the upper reservoir with electrophoresis buffer.

10. Remove the screen and attach the top (+) electrode. Connect the peristaltic pump to the buffer reservoirs; the upper reservoir buffer is exchanged at 1 ml/min while the lower reservoir is exchanged at 5 ml/min during the run.

Start the electrophoresis

11. Carry out electrophoresis at a constant current of 10 mA (3 V/cm field) for a total of 40 min. At two times during the run, allow 6 ml of 10% Ficoll 70 in electrophoresis buffer to drip slowly (1 ml/min) from the bottom of the electrophoresis chamber, then replace with 6 ml of fresh 10% Ficoll 70.

Note that electrophoresis of vesicles with a negative surface charge occurs upward.

Replacement of some of the Ficoll 70 is a precaution taken to prevent formation of a low-conductivity layer at the surface of the cation-permeable membrane at the base of the chamber.

Stop the electrophoresis and unload the chamber

12. After ending the run, drain the upper buffer reservoir and reattach the loading inlet above the electrophoresis chamber.

13. Unload the contents of the chamber by upward displacement by pumping 10% Ficoll 70 through the inlet at the bottom of the chamber. Collect the contents in 25- to 30-fractions and use for further analysis.

Figure 4.2.6 (from Tulp et al., 1994) illustrates clearly the distinct distributions of different organelles that have been resolved from a crude microsomal preparation of melanoma cells by density gradient electrophoresis.

BASIC PROTOCOL 5

SOLID-PHASE IMMUNOADSORPTION

Solid-phase immunoadsorption using specific antibodies is a powerful technique for isolating cellular organelles that can be used on both the preparative and analytical levels. The procedure requires a high-quality antibody that reacts to an antigenic epitope exposed on the surface of the organelle of interest; the antigen must be reasonably specific to the organelle of interest. The antibody is adsorbed to a support (e.g., fixed *Staphylococcus aureus* cells, protein A–Sepharose, or magnetic beads), and the organelles of interest bind to the antibody support.

The procedure presented below describes use of antibody-coated magnetic beads, an approach developed for organelles by Gruenberg and Howell (1986). An antibody to the cytoplasmic tail of the polymeric immunoglobulin receptor is bound to the beads coated with secondary antibody; it is then used to isolate relatively large organelles—stacked elements of the Golgi complex—and vesicles that can be induced to bud in vitro from the stacked Golgi elements (Salamero et al., 1990).

CU IASI CENTRAL UNIVERSITY LIBRARY

Materials

5 mg/ml BSA in PBS
Primary antibody that selectively recognizes an antigenic epitope present on the exposed surface of the vesicle of interest
5 mg/ml BSA in 0.25 M sucrose (ultrapure; e.g., ICN Biochemicals)/0.1 M potassium phosphate (pH 6.65)
Rat starved overnight and freshly sacrificed
Homogenization medium: 0.5 M sucrose/0.1 M potassium phosphate (pH 6.65)/5 mM $MgCl_2$
1.25 M, 1.3 M, and 1.4 M sucrose (ultrapure) in 0.1 M potassium phosphate (pH 6.65)/5 mM $MgCl_2$
4.5-μm-diameter magnetic beads coated with sheep anti-mouse Fc antibody (Dynal)
Magnetic collection device (e.g., Dynal)
End-over-end rotator capable of slow rotation (2 to 4 rpm; e.g., Pelco rotator, modified)
10-ml and 38-ml centrifuge tubes suitable, respectively, for Beckman Type 50 and SW28 rotors

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after removing and weighing tissue should be conducted at 0°C (ice bucket) or 4°C (cold room).

Coat the magnetic beads with primary antibody

1. Wash an appropriate amount of 4.5-μm-diameter magnetic beads twice with 1 ml of 5 mg/ml BSA in PBS in a microcentrifuge tube. Collect beads with a magnetic collection device between washes. Resuspend to a concentration of 2 mg beads/ml in the same medium.

   Coating the beads with antibody (steps 1 to 4) is usually done the day before the rest of the experiment. The beads are treated with protein to block nonspecific adsorption. Most procedures call for using bovine serum albumin (5 mg/ml in PBS or in buffered 0.25 M sucrose); one recent protocol recommends use of fetal bovine serum (3% in PBS) as the best way to reduce nonspecific binding (Saucan and Palade, 1994).

   Magnetic concentration is very quick and requires <1 min per wash. Dynal markets a number of magnetic collection devices, one of which is appropriate for microcentrifuge tubes. Alternatively, a plate magnet (Edmund Scientific) can be used beneath a cell culture dish (Howell et al., 1989).

   In addition to 4.5-μm beads, Dynal also markets 2.8-μm beads, beads coated with anti-mouse antibody, and tosyl-activated beads that can be custom-coupled to the antibody of choice by the investigator using a very simple procedure described by the manufacturer.

2. Add primary antibody (in 1 ml of 5 mg/ml BSA in PBS) to 2-fold excess over the amount of bound secondary antibody. Incubate 4 hr to overnight at 4°C in a microcentrifuge tube on an end-over-end rotator set at 2 to 4 rpm.

   Information regarding the amount of secondary antibody bound to the magnetic beads is provided by the manufacturer.

   A rotator for electron microscopy samples available from Pelco can be easily modified for the slow rotation needed for this protocol.

3. Wash the beads by adding 1 ml of 5 mg/ml BSA in PBS, 4°C, then collecting the

BOSTON UNIVERSITY LIBRARY

beads magnetically or by microcentrifugation (30 sec at 10,000 rpm). Repeat twice with 5 mg/ml BSA in 0.25 M sucrose/0.1 M potassium phosphate, pH 6.65.

In general, a control for nonspecific binding can be run in parallel using beads that have been coated with an irrelevant primary antibody.

Prepare sample for immunoadsorption

Example: Prepare sample enriched in stacked Golgi complexes from rat livers:

4. On the same day the immunoadsorption experiment is to be done, sacrifice a rat that has been starved overnight (to deplete hepatic glycogen) and remove liver. Weigh liver, mince, homogenize, and filter as for velocity differential centrifugation (see Basic Protocol 1), except homogenize at 20% (w/v) in 0.5 M sucrose/0.1 M potassium phosphate/5 mM $MgCl_2$ homogenization medium.

   This method for preparing a partially purified fraction enriched in stacked Golgi complexes from rat livers is based on the procedure of Leelavathi et al. (1970).

5. Prepare a postnuclear supernatant (PNS) by centrifuging sample as for differential centrifugation by velocity (see Basic Protocol 1, step 4).

6. Place a 4-ml cushion of 1.3 M sucrose/0.1 M potassium phosphate/5 mM $MgCl_2$ into a 10-ml centrifuge tube, and layer 6 ml PNS on top. Centrifuge 60 min at 105,000 × *g* (in Type 50 rotor), 4°C.

7. Collect the band at the surface of the 1.3 M sucrose layer and adjust to 1.1 M sucrose using homogenization medium.

8. Prepare a second set of discontinuous gradients containing 6 ml each of 1.4 M, 1.3 M, and 1.25 M sucrose in 0.5 M potassium phosphate/5 mM $MgCl_2$. Layer 6 ml of the adjusted sample (step 7) over each gradient, overlay with homogenization medium to fill the tubes, and centrifuge 90 min at 80,000 × *g* (in SW28 rotor), 4°C.

9. Collect the Golgi fraction at the interface between the load and the 1.1 M sucrose layer. Adjust to 0.25 M sucrose and 5 mg/ml BSA. Place on ice.

   The Golgi fraction is now ready to be used for immunoadsorption (which should be done on the same day). The fraction should be assayed for protein content and maintained on ice until use.

Adsorb organelles to antibody-coated beads

10. Add a sample of the organelle fraction (~0.5 mg protein in 0.3 to 0.4 ml of 0.25 M sucrose/5 mg/ml BSA) to 1 mg antibody-coated magnetic beads in 0.6 to 0.8 ml of 5 mg/ml BSA in PBS. Incubate 3 hr at 4°C with end-over-end rotation to allow binding to occur.

    Generally, the optimal ratio of input fraction to coated beads is determined in a preliminary binding experiment in which several 1-mg aliquots of beads are incubated with increasing amounts of the organelle fraction to determine the saturation point of binding. Bound and free organelles can be assessed by immunoblotting. For functional studies involving vesicle budding from adsorbed organelles, it is necessary to saturate antigen binding sites so that the vesicles can't bind once they have budded. Salamero et al. (1990) reached saturation at 0.5 mg (protein) of Golgi fraction per mg of beads.

Wash away unadsorbed organelles

11. Wash the coated beads with 0.25 M sucrose/5 mg/ml BSA. Repeat as many times as needed to remove all unadsorbed organelle, collecting the beads magnetically between washes.

    The number of washes needed should be determined in the preliminary immunoblotting experiment mentioned above.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

For adsorbed small vesicles (e.g., endosomes), the concentration device built for microcentrifuge tubes is satisfactory. For large organelles such as the stacked Golgi complexes, it is preferrable to use culture dishes and a plate magnet so that the adsorbed organelles are not damaged or dislodged by mechanical shear.

12. Use the immunoadsorbed fraction for further studies.

Examples of further applications include treatment with SDS solubilization buffer to desorb bound protein for SDS-PAGE and immunochemical analysis; suspension in fixative followed by preparation for electron microscopic analysis; incubation with a second primary antibody followed by a colloidal gold–conjugated secondary antibody to test for co-localization with the immunoadsorbing antigen by immunoelectron microscopy (e.g., Laurie et al., 1993); and functional studies of vesicle trafficking (Salamero et al., 1990).

PURIFICATION BY LECTIN ADSORPTION

BASIC PROTOCOL 6

Lectin adsorption has proven to be particularly useful for plasma membrane isolation and to a lesser degree for isolation of endosomes and lysosomes that have loaded by endocytosis of lectin conjugates at the cell surface. The latter procedures fall into the category of fractionation by density perturbation (Basic Protocol 7). In some procedures, the lectin conjugate is added to intact cells, thereby guaranteeing specific binding to plasma membrane; this approach appears to be applicable to cultured cells but not to tissues. In other procedures that are applicable to tissue samples, immobilized lectins can be used to adsorb selectively to plasma membrane vesicles in cell homogenates or partially purified fractions (e.g., crude microsomes). This strategy is possible because following cell or tissue disruption during homogenization, plasma membranes vesiculate with the ectodomain (glycosylated surface) facing outward, whereas most cytoplasmic organelles retain a cytosolic-surface-outward orientation. Once the fraction is bound to the lectin and washed free of unbound organelles, it can be eluted by competing the interaction between lectin and vesicles using the appropriate hapten sugar.

In this protocol, wheat germ agglutinin (WGA) affinity chromatography is used to purify apical plasma membranes from homogenates of pancreatic acinar cells (Paul et al., 1992). WGA is a lectin that binds both *N*-acetylglucosamine (GlcNAC) and *N*-acetylneuraminic acid (Neu5Ac) residues in glycoproteins, and interactions with WGA can be competed with free *N*-acetylglucosamine, which is relatively inexpensive. Additional guidelines for lectin affinity chromatography are presented in *UNIT 9.1*.

Materials

Freshly sacrificed Sprague-Dawley rat (200 to 275 g), fasted overnight
Homogenization medium (see recipe; add 0.1 mM PMSF just before fractionation), 0°C
0.2 M KCl/0.2 M NaBr/50 mM Tris·Cl, pH 6.8
50 mM Tris·Cl, pH 6.8
Wheat germ agglutinin (WGA) conjugated to Sepharose (Pharmacia Biotech), preequilibrated with 50 mM Tris·Cl, pH 6.8
0.1 M *N*-acetylglucosamine (e.g., Sigma) in 50 mM Tris·Cl, pH 6.8

Motor-driven Teflon-glass homogenizer
Cheesecloth
Centrifuge capable of producing a field of 25,000 × *g* and equipped with a fixed-angle rotor
Centrifuge tubes
5-ml chromatography column

BOSTON CENTER UNIVERSITY LIBRARY

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after removing and weighing tissue should be conducted at 0°C (ice bucket) or 4°C (cold room).

Prepare a crude plasma membrane fraction

1. Remove pancreas from rat, weigh (generally 0.6 to 1.0 g tissue per rat), submerge in 0°C homogenization medium, and mince coarsely with scissors.

   Paul et al. (1992) used 6 g of pancreas. More than one rat may be required.

2. Homogenize at 10% (w/v) in homogenization medium by 10 strokes with a Teflon-glass homogenizer. Filter the homogenate through four layers of cheesecloth. Remove a small aliquot (~1% of total volume) for assay of marker activities.

3. Centrifuge 25 min at 120 × *g*, 4°C, to remove large cellular debris (most nuclei and larger).

4. Collect the supernatant and centrifuge 15 min at 13,000 × *g*, 4°C, to pellet zymogen granules and mitochondria.

5. Collect the supernatant and centrifuge 60 min at 25,000 × *g*, 4°C, to pellet plasma membranes and other vesicles.

6. Discard the supernatant and resuspend the pellet in 1 to 2 ml of 0°C homogenization medium. Remove an aliquot (~1% of total volume) and assay for marker activities.

   Marker assays include: (1) γ-glutamyl transferase, an apical plasma membrane marker (Orlowsky and Meister, 1963); (2) Na,K-ATPase, a basolateral plasma membrane marker (Baykov et al., 1988); and (3) alkaline phosphatase, a duct cell plasma membrane marker (Emmelot and Bos, 1966).

   It is reported that 65% of the marker activity of the apical plasma membrane, γ-glutamyl transferase, is present in this fraction (Paul et al., 1992).

   If activities are being followed during the course of purification, assaying all fractions generated at each step is recommended so that it will possible to account for all activity.

7. Dilute the rest of the resuspended membranes 10-fold with 0.2 M KCl/0.2 M NaBr/50 mM Tris·Cl, pH 6.8. Resediment by centrifuging 60 min at 25,000 × *g*, 4°C.

   NaBr is a chaotropic agent that has been used frequently in fractionating pancreas to promote desorption of extrinsic proteins from membrane vesicles.

8. Resuspend the pellets in 3 ml of 50 mM Tris·Cl, pH 6.8. Mix with 3 ml of WGA-Sepharose preequilibrated in 50 mM Tris·Cl, pH 6.8. Gently mix for 30 min in a closed tube, then transfer the entire mixture to a 5-ml chromatography column.

9. Wash the column after loading with at least 15 ml (5 vol) of 50 mM Tris·Cl, pH 6.8.

10. Elute the bound vesicles using 0.1 M *N*-acetylglucosamine in 50 mM Tris·Cl, pH 6.8. Concentrate the membrane-containing fractions as necessary by centrifuging 60 min at 25,000 × *g*, 4°C.

    Most of the membrane vesicles elute within 2 to 4 ml. This can be confirmed by assaying γ-glutamyl transferase of the fractions (a very easy spectrophotometric assay; Orlowski and Meister, 1963).

    Measurements of the specific activity of γ-glutamyl transferase (per protein) in the homogenate and the final purified membranes indicates that the purification is 75-fold, which is excellent for plasma membranes.

SCU IAS / CENTRAL UNIVERSITY LIBRARY

DENSITY SHIFT USING DIGITONIN

Density-shift techniques have found use in both analytical and preparative centrifugation procedures. In this approach, the sample to be separated is subjected to a treatment that differentially alters the densities of the component organelles, which are then separated by centrifugation. The following density-shift technique (based on the work of Amar-Costasec et al., 1974) involves the use of digitonin and capitalizes on differences in cholesterol content in the membranes of various cell organelles. Controlled, sublytic concentrations of digitonin are applied to the membranes, leading to the formation of 1:1 molecular complexes with cholesterol, and these complexes result in increased buoyant density during cell fractionation. The magnitude of the effect varies depending on the cholesterol content of different organelle membranes; consequently, different organelles exhibit distinct density shifts as judged from the distribution of marker activities. The example given is for microsomes from rat liver but can be adapted to membranes from other sources.

Materials

Rat starved overnight to deplete glycogen stores and freshly sacrificed
Homogenization medium: 0.25 M sucrose (ultrapure; e.g., ICN Biochemicals)/3 mM imidazole (pH 7.4)
20 mg/ml digitonin stock solution (see recipe)
10% (w/v) Triton X-100
Digitonin density shift gradient stock solutions (see recipe)
Sample for treatment and analysis

Motor-driven Teflon-glass homogenizer (type C, A.H. Thomas)
Cheesecloth
Low-speed refrigerated centrifuge
Ultracentrifuge with fixed-angle (e.g., Beckman 70Ti), and swinging-bucket rotors (e.g., Beckman SW28)
Ultracentrifuge tubes to fit rotors
Gradient-forming device (e.g., Hoefer Pharmacia)

Additional reagents and equipment for microsomal fraction preparation (see Basic Protocol 1)

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after removing and weighing tissue should be conducted at 0°C (ice bucket) or 4°C (cold room).

Prepare crude microsomal sample

1. Remove liver from a sacrificed rat (6 to 7 g tissue) and prepare total microsomal preparation as in differential centrifugation by velocity (see Basic Protocol 1, steps 1 to 8 and 11 to 12), except using homogenization medium containing 3 mM imidazole.

   Imidazole (pH 7.4) was the buffer used when the procedure was devised; MOPS or HEPES can be substituted at the same concentration.

2. Resuspend the microsomal pellet thoroughly in homogenization medium using a Teflon-glass homogenizer and wash by repelleting under the same conditions used to pellet the microsomes initially (see Basic Protocol 1, steps 11 and 12).

3. Resuspend the pellet (total washed microsomes) in homogenization medium, using 1 ml medium per 1 g liver used in step 1 and keep on ice until use.

BCM INST CENTRAL UNIVERSITY LIBRARY

Determine the digitonin concentration to use for density shift by dose-response assay

4. For liver microsomes, proceed to steps 6 to 8; for membranes from other tissues, determine the digitonin concentration to use for density shift by dose-response assay as follows: Prepare two sets of samples (100 µl/sample) each containing identical amounts of resuspended microsomes. To each set add 270 µl of appropriate digitonin solution to give final concentrations of 0 to 9 mg/ml. To one set, also add Triton X-100 to 0.2% final concentration; to the other set, add equal amounts of water. Incubate 15 min at 0°C.

   Be sure to add the digitonin in the same final volume and as a solution that contains 0.25 M sucrose. Dilute the 20 mg/ml digitonin stock solution to 15 mg/ml using 1 M sucrose; then mix 0.25 M sucrose with 15 mg/ml digitonin in sucrose to give 1.5, 3, 4.5, 6, and 12 mg/ml digitonin, corresponding to final concentrations of 1.1, 2.2, 3.3, 4.4, and 8.8 mg/ml digitonin respectively after addition to samples.

   The Triton X-100 treatment solubilizes the membrane; this set of samples is used to assay total activity. The set of samples treated with water is used to determine latency of activity—i.e., only limited activity will be detected until digitonin reaches a concentration that causes membrane lysis, at which point nearly the same activity will be detected as in the presence of Triton.

5. Assay the samples for the marker activities of specific organelle(s)—i.e., for the presence of an enzyme activity or other marker that is located in the interior of the vesicle of interest. Determine the highest digitonin concentration that does not cause membrane lysis.

   In the dose-response performed by Amar-Costasec et al. (1974), 2.7 vol digitonin-containing solution was added to each sample, and the samples were assayed for ER nucleoside diphosphatase and Golgi galactosyltransferase activities. The appropriate sublytic concentration was determined to be 1.7 mg/ml digitonin (Merck), which the authors estimate corresponds to a molar ratio of digitonin/cholesterol of slightly greater than 1:1.

Prepare sucrose density gradients

6. In the bottom of each centrifuge tube, place a cushion of 2.7 M sucrose.

   For an SW28 tube with 37-ml capacity, this cushion is 3 ml.

7. Using the gradient-forming device and working at room temperature, generate a linear sucrose gradient above the cushion extending from 1.9 M sucrose (density 1.25 g/ml) to 0.8 M sucrose (density 1.10 g/ml) as follows: place the 0.8 M sucrose gradient stock in the back chamber of the gradient maker (15 ml for SW28 tube) and allow it to flow into the junction between the two chambers. Place 15 ml of 1.9 M sucrose gradient stock in the mixing chamber. Open the junction between the chambers of the gradient maker, turn on the stirring device in the mixing chamber, and activate the peristaltic pump to generate the gradient. Once the gradient is generated, chill in a 4°C cold room.

   Because of the high molarity and viscosity of the 1.9 M sucrose, it is placed in the mixing chamber and the gradient is generated high density first. Thus the outlet tube must remain above the surface of the gradient as it is formed in the centrifuge tube (see Fig. 4.1.2). The gradients are prepared at room temperature to decrease viscosity.

Treat microsomes and subject to density gradient centrifugation

8. Prepare two samples from the same batch of microsomes used for the dose-response assay (steps 4 and 5)—1 ml each, if an SW28 rotor will be used, or smaller if scaled down—in homogenization medium. Add 2.7 vol of appropriate-concentration ice-cold digitonin solution to one of the samples. Incubate 15 min on ice.

CU IASI (CENTRAL UNIVERSITY LIBRARY)

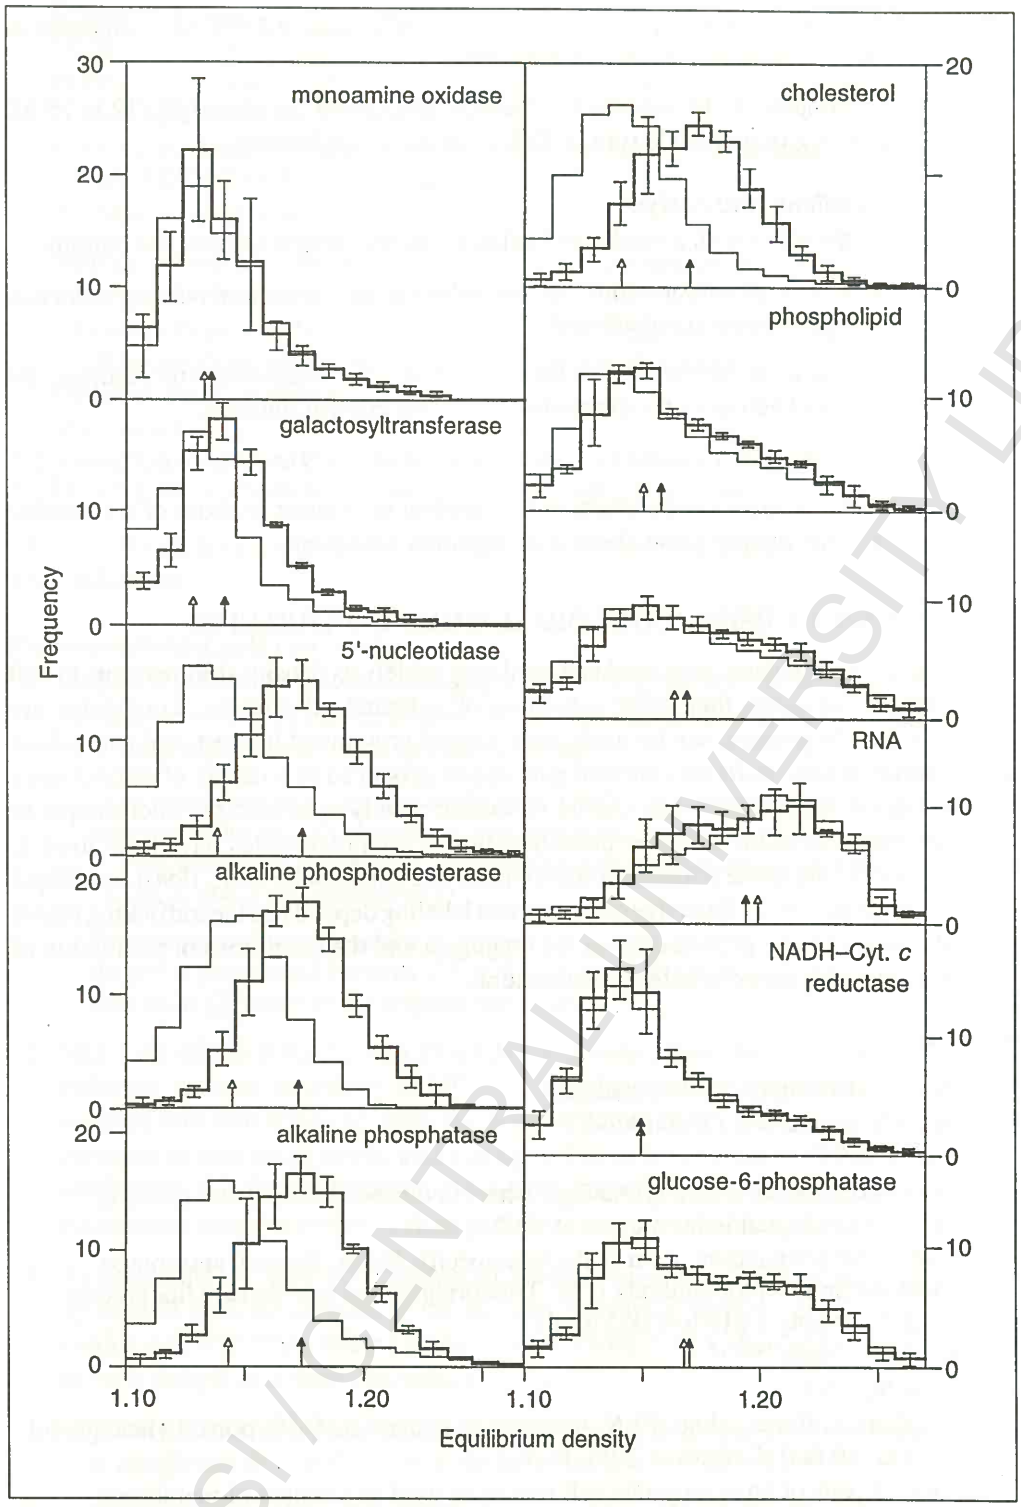

Figure 4.2.7 Distribution of marker activities for various organelles after equilibrium centrifugation. Thin lines and open vertical arrows show the distribution and median density, respectively, of control samples; bold lines and filled vertical arrows show the distribution and median density, respectively, of digitonin-treated samples. Activity profiles are determined across the entire gradient (1.10 to 1.27 g/ml); digitonin treatment shifts the activity profile to higher density in proportion to the amount of cholesterol in the membrane. ER (glucose-6-phosphatase; NADH–cytochrome *c* reductase) and mitochondrial (monoamine oxidase; NADH–cytochrome *c* reductase) marker activities are practically unshifted, corresponding to the negligible cholesterol content of these organelles. Golgi (galactosyltransferase) and plasma membrane (5′-nucleotidase, alkaline phosphodiesterase, and alkaline phosphatase) marker activities are shifted by 0.015 and 0.030 to 0.036 g/ml (median density), respectively. From Amar-Costasec et al. (1974) by permission of The Rockefeller University Press.

DEAKIN UNIVERSITY / CENTRAL LIBRARY

For liver microsomes, Amar-Costasec et al. (1974) used 0.235% (w/v) digitonin in 0.25 M sucrose to give 1.7 mg/ml digitonin.

9. Load the samples on the continuous gradients and centrifuge overnight (12 to 15 hr) at ~82,500 × *g* (e.g., 26,000 rpm in SW28) to reach equilibrium.

Collect the gradients and analyze

10. Puncture the tubes with a needle and collect fractions dropwise from the bottom.

Because the high concentration sucrose solutions are so viscous, manual collection with a micropipettor is not advised.

11. Assay the fractions for the marker activities of specific organelles and compare the distributions of activities for digitonin-treated and control samples.

Examples of results obtained by Amar-Costasec et al. (1974) are shown in Figure 4.2.7.

12. If relevant, compare the distribution of a protein of interest to those of the marker proteins in the presence and absence of digitonin treatment.

BASIC PROTOCOL 8

DENSITY SHIFT USING COLLOIDAL GOLD CONJUGATES

Colloidal gold conjugates have not been used very widely as density shift reagents in cell fractionation; however, they offer a number of potential advantages. Conjugates are relatively easy to prepare, can be made with various proteins of interest, and can induce a substantial density shift; the colloidal gold can be produced in a variety of distinct sizes and, because it scatters electrons, can be visualized readily in an electron microscope. In the following procedure, different protein–colloidal gold conjugates have been used to prepare specific organelle fractions from lymphocytes (Beaumelle et al., 1990) and HEp.2 cells (Futter et al., 1995). Selective compartment labeling depends on the trafficking routes normally taken by the protein used in the conjugate and the conditions of incubation of the conjugate with the cells before fractionation.

Materials

1% (w/v) trisodium citrate dihydrate
1% (w/v) tannic acid (Mallinkrodt)
25 mM K_2CO_3
1% (w/v) chloroauric acid ($HAuCl_4$; Fisher) in twice-distilled water (store in brown bottle; stable for months at 4°C)
Proteins for conjugation: ricin (galactose-specific lectin; Sigma), anti-mouse transferrin receptor antibody (I.W. Trowbridge), and low-density lipoprotein (LDL; density 1.019 to 1.063 g/ml)
10% (w/v) NaCl
1% (w/v) BSA
Phosphate-buffered saline (PBS, *APPENDIX 2E*) containing 0.5% polyethylene glycol (PEG) 20,000 (Carbowax 20M, Fluka)
Cultured cells of an appropriate cell line to be used as a source of membrane fractions: e.g., BW 5147 mouse T cell lymphoma cells (characterized by I.W. Trowbridge, Salk Institute; available from ATCC) or HEp.2 cells (ATCC CCL23)
Dulbeccos Modified Eagle Medium (DMEM) containing 100 mg/ml BSA
DMEM containing 1% horse serum
DMEM containing 5 mg/ml BSA
PBS (*APPENDIX 2E*)
Hypoosmotic homogenization medium (see recipe)
Hyperosmotic buffer (see recipe)

CU IASI CENTRAL UNIVERSITY LIBRARY

RNase (Sigma)
DNase I for treating cell homogenates (Sigma)
Pellet resuspension solution: 0.25 M sucrose (ultrapure; e.g., ICN Biochemicals)/1 mM EDTA/10 mM Tris acetate (pH 8.0)
Continuous density gradient solutions: 30% and 60% (w/v) sucrose (ultrapure) in 1 mM EDTA/10 mM Tris acetate (pH 7.5)
2.5 M sucrose in water

Nitrogen bomb and Dounce homogenizer for homogenization
Low-speed refrigerated centrifuge
Ultracentrifuge with fixed-angle and swinging-bucket rotors (e.g., Beckman ultracentrifuge with Type 50 and SW40 or SW41 rotors)
Gradient-forming device
Micropipettor

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after harvesting cells should be conducted at 0°C (ice bucket) or 4°C (cold room).

Prepare colloidal gold conjugates

1. Prepare a reducing mixture containing 4 ml of 1% trisodium citrate dihydrate, 0 to 5 ml of 1% tannic acid (depending on the particle size desired), and the same volume of 25 mM K_2CO_3. Add Milli-Q water to 20 ml.

   As discussed in detail by Slot and Geuze (1985), the amount of tannic acid added determines the size of the particles obtained in the gold sol. Addition of 0.01, 0.1, 0.5, or 5 ml tannic acid yields (after the following steps) gold particles of average diameter 16, 10, 5, and 3 nm, respectively.

   Potassium carbonate is added to compensate for the acid from the tannic acid so that the pH is maintained between 7.5 and 8. Slot and Geuze used glass-distilled (rather than Milli-Q) water in the original procedure.

2. Mix 1 ml of 1% $HAuCl_4$ with 79 ml Milli-Q water. Heat the gold solution and the reducing mixture separately to 60°C, then rapidly mix together with stirring. The solution will turn wine red when the gold sol forms (this takes a few seconds in the presence of maximum tannic acid and up to 1 hr in the absence of tannic acid). After sol formation is finished, continue to heat the samples until boiling. Allow to cool to room temperature and store in clean glass containers until used (up to several months).

3. To determine the minimum amount of protein required to stabilize the gold sol, set up several 0.25-ml samples of sol and add increasing amounts of the protein to be conjugated (0 to 10 µg using 2 mg/ml stocks in water). Mix, then add 10% (w/v) NaCl to each sample to a final concentration of 1%.

   If the solution turns blue, then the gold sol has flocculated and the amount of protein is insufficient for stabilization; if the solution stays red, the sol is stable.

   Slot and Geuze (1985) state that blue color development is slow and subtle in samples that retain excess tannic acid. In this case they recommend adding 0.1% to 0.2% H_2O_2 to destroy the tannic acid and facilitate normal color development.

   Ricin, anti-mouse transferrin receptor antibody, and LDL are the proteins conjugated in the work of Beaumelle et al. (1990), which is being used as an example. Ricin is a galactose-specific lectin (CAUTION: *Ricin is a toxin and must be handled with care). Anti-mouse transferrin receptor antibody is discussed in Lesley et al. (1984). Low-density lipoprotein (LDL; density 1.019 to 1.063 g/ml) is purified from fresh human plasma*

BOSTON UNIVERSITY MEDICAL LIBRARY

using the procedure of Havel et al. (1955), which involves flotation from NaCl/KBr solutions.

4. Prepare a supply of the stable conjugate by adding more than twice the minimum amount of stabilizing protein with stirring. After 1 min, add BSA to 0.1% final (for added stability).

   Protein-gold conjugates formed this way are quite uniformly sized.

   Beaumelle et al. (1990) conjugated 1.9 mg ricin and 1.0 mg anti-transferrin receptor antibody with 100 ml gold.

5. Pellet the protein-gold conjugates in a fixed-angle rotor for 45 min at 50,000 × *g* (for gold ≥10 nm) *or* at 125,000 × *g* (for gold <10 nm), 4°C. The pellets usually have a tightly packed portion that adheres to the tube and a larger loose portion that is easily withdrawn with a pipet. Take only the latter.

6. Resuspend the protein-gold conjugate in 3 to 5 ml PBS containing 0.05% PEG 20,000 (as an extra stabilizer).

   Where protein-gold conjugates are made with serum LDL, the conjugation procedure used is different (Handley et al., 1981), and the conjugate is used immediately. A solution of 1.5 µg LDL in 0.5 ml of 50 mM EDTA (pH 5.5) is added with rapid stirring to 5.0 ml colloidal gold (prepared at the same pH using sodium citrate). The LDL-gold conjugate is sedimented away from excess LDL through a 35% sucrose cushion (centrifuging 20 min at 9000 × g) in a swinging-bucket rotor. The loose pellet is resuspended in cell culture medium and used directly for incubation.

Incubate protein-gold conjugates with cells

7a. *For isolation of plasma membranes*: Incubate 10^8 cultured cells 1 hr on ice in 5 ml DMEM containing 100 µg/ml BSA and 200 µl gold-ricin conjugate (from step 6).

   This step stops all membrane traffic. Beaumelle et al. (1990) report that the lectin concanavalin A does not bind to the plasma membrane sufficiently to cause a density shift during subsequent fractionation.

7b. *For isolation of endosomes*: Incubate 10^8 cultured cells 2 hr at 22°C in 5 ml DMEM containing 100 µg/ml BSA and 130 µl anti-mouse transferrin receptor antibody–gold conjugate.

   Incubation at 22°C retards both recycling back to the cell surface and trafficking from endosomes to lysosomes. Note that under steady-state conditions, 80% of transferrin receptors in these cells are concentrated in endosomes.

7c. *For isolation of coated pits*: Incubate 10^8 cultured cells 2 hr at 10°C in 5 ml DMEM containing 100 µg/ml BSA and 130 µl anti-mouse transferring receptor antibody–gold conjugate.

   Incubation at 10°C inhibits internalization of coated pits. Note that a large fraction of the transferrin receptor that is present on the cell surface is concentrated in coated pits.

7d. *For isolation of lysosomes*: Incubate 2 to 5 × 10^8 cultured cells 18 hr at 37°C in DMEM containing 1% horse serum, 5 mg/ml BSA, and 0.8 mg LDL-gold conjugate. Withdraw the medium with a pipet and replace with DMEM containing 5 mg/ml BSA and 150 µg/ml LDL. Incubate an additional 3 hr at 37°C.

   The second incubation (with unconjugated LDL) serves to chase internalized LDL to lysosomes and compete away any surface-associated LDL-gold.

8. After incubation, wash the cells twice with DMEM containing 100 µg/ml BSA and once with PBS (both at the temperature used in step 7a-d), then chill on ice.

CCU IASI / CENTRAL UNIVERSITY LIBRARY

Lyse and homogenize labeled cells and prepare postnuclear supernatant

9. Wash the cells once with hypoosmotic homogenization medium, then scrape (or resuspend, if not attached) into the same buffer, using 1 ml buffer per 5×10^7 cells.

10. Place the cells in a nitrogen bomb for 20 min at 750 lb/in^2 and release pressure according to manufacturer's instructions. Transfer the initial homogenate to a Dounce homogenizer (without altering the composition of the medium) and homogenize with 20 strokes.

    The initial homogenization using the nitrogen bomb results in ~30% lysis of the BW 5147 cells (judged by trypan blue exclusion; UNIT 5.5). After Dounce homogenization lysis is ~90% with no increase in nuclear damage.

    If a nitrogen bomb is not available, then other homogenization procedures should be tried. Other publications from the same laboratory that developed this procedure report homogenization by passage 15 times through a syringe equipped with a 21-G needle (Futter and Hopkins, 1989) and by repeated passage through a micropipet tip (Beardmore et al., 1987). To a large extent, the homogenization procedure that works best will depend on the type of cells being studied.

11. Add 0.1 vol hyperosmotic buffer and centrifuge 5 min at 800 × *g*, 4°C.

12. Remove the supernatant (PNS). Add 0.1 mg/ml RNase and 0.2 mg/ml DNase I and incubate 3 min at 37°C.

    This step digests any accessible chromatin and RNA and improves the ensuing purification by decreasing aggregation of the total membrane pellet that is prepared in the next step.

Pellet the total membranes of the PNS

13. Pellet organelles in the PNS by centrifuging 30 min at 120,000 × *g*, 4°C, in a fixed-angle rotor.

    These centrifugation conditions will reliably pellet organelles that contain bound colloidal gold.

14. Resuspend the pellets in pellet resuspension solution, using a small-volume Dounce homogenizer if necessary to obtain thorough dispersal.

Prepare and run the continuous sucrose gradients

15. Place sucrose cushions consisting of 0.5 ml of 2.5 M sucrose in the bottom of 13-ml ultracentrifuge tubes.

    Instructions are given for 13-ml tubes and a SW40 or SW41 rotor, but may be adjusted to different sizes if desired.

16. In each tube, generate a 12-ml continuous (60% to 30%) sucrose gradient above the cushion using the gradient solutions as follows: place 6 ml of 30% sucrose solution in the back chamber of the gradient maker, and fill the junction tube to the mixing chamber. Place 6 ml of 60% sucrose solution in the mixing chamber. Open the junction between chambers, start stirring and pumping, and generate gradients (high density first) above the cushion.

    The delivery tube from the gradient-forming device should be kept above the surface of the fluid in the centrifuge tube.

17. Load 0.5-ml aliquots of the resuspended pellet on top of each gradient and centrifuge 16 hr at 200,000 × *g*, 4°C, in an ultracentrifuge with swinging-bucket rotor (e.g., SW40 or SW41).

BOWLING GREEN STATE UNIVERSITY LIBRARY

Collect the fractions for analysis

18. Unload the gradient from the top in 1-ml fractions. Manual collection with a micropipettor will work fine as long as the high-viscosity sucrose is collected slowly. Otherwise use an automated collection device (Buchler, Nyegaard, or MSE Scientific; see Alternate Protocol 1, step 11).

    In all cases the organelles that have been purified by density shift are found in the fraction that is just above the pinkish pellet.

19. Analyze the fractions by assaying for marker activities or for protein by two-dimensional SDS-PAGE (*UNIT 10.4*), electron microscopy, and immunoprecipitation or immunoblotting.

    In the published procedures, the authors also carried out all these procedures using ^{125}I-radiolabeled protein-gold conjugates and were able to estimate yields of the various organelles by the density shift technique. They obtained 40%, 32%, 10%, and 16% of the associated radiolabel in the high-density fractions of plasma membranes, endosomes, coated pits, and lysosomes, respectively.

BASIC PROTOCOL 9

EXTRACTION OF EXTRINSIC PROTEINS FROM MEMBRANES USING SODIUM CARBONATE

The methods for cell fractionation presented elsewhere in this unit focus mostly on purifying specific organelles without further subfractionation into component parts. For many studies that focus on membranes of organelles or on specific membrane-associated proteins, it is desirable to have an easy way to categorize integral and extrinsic polypeptides. Extraction with 0.1 M sodium carbonate (pH 11.5) at 0°C (Fujiki et al., 1982) has gained widespread popularity as an easy and efficient method for selectively stripping extrinsic proteins off membranes without affecting the disposition of integral components (including transmembrane and lipid-anchored proteins). The treatment converts vesicles into small membrane sheets, releasing soluble and adsorbed proteins in the process. The membranes are recovered after the treatment by centrifugation. Carbonate extraction has been applied to numerous organelles including endoplasmic reticulum, Golgi, secretory vesicles, plasma membranes, lysosomes, and peroxisomes.

Materials

0.1 M sodium carbonate (Na_2CO_3), pH 11.5, ice cold
0.3 M sucrose (ultrapure; e.g., ICN Biochemicals), buffered to pH 7 to 7.5 (e.g., with 10 mM Tris·Cl)
Cell organelle or membrane fraction to be treated
Ultracentrifuge with swinging-bucket rotor

NOTE: Prepare solutions with Milli-Q-purified water or equivalent.

NOTE: All operations after removing and weighing tissue should be conducted at 0°C (ice bucket) or 4°C (cold room).

1. Pellet the organelles or vesicles to be extracted by centrifugation, using conditions described in the appropriate basic or alternate protocol.
2. Resuspend the pellets in a small amount of buffered sucrose sufficient to obtain a well-dispersed suspension.
3. Dilute the sample 50× to 1000× with ice-cold 0.1 M Na_2CO_3. Maintain 30 min on ice.

    A final protein concentration of 10 to 1000 μg/ml is generally appropriate. Assay protein content if there is concern that this range is exceeded.

CU IAST / CENTRAL UNIVERSITY LIBRARY

4. Place a small cushion of 0.3 M buffered sucrose in a centrifuge tube (~10% of the volume of the tube), then carefully layer the organelle suspension on top. Pellet the membranes by centrifuging 1 to 2 hr at ~150,000 × *g*, 4°C.

   Although not specified in the original procedure, the buffered sucrose cushion prevents formation of a rock-like pellet that is often very difficult to resuspend.

5. Resuspend the pellets and use for assays.

   Although the high-pH treatment on ice generally does not affect subsequent immunoprecipitations, it can inhibit some enzyme activities (check in a preliminary experiment).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see ***APPENDIX 2E****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Digitonin density shift gradient stock solutions

Prepare three separate stock solutions:

0.8 M sucrose/3 mM imidazole, pH 7.4 (density 1.10 g/ml)
1.9 M sucrose/3 mM imidazole, pH 7.4 (density 1.25 g/ml)
2.7 M sucrose (density 1.34 g/ml)

The 2.7 M sucrose is used for the cushion and contains no buffer. Sucrose should be ultrapure (e.g., ICN Biochemicals).

Sucrose stocks can be filtered using 1.2-μm Millipore filter (or equivalent) and stored at least 2 weeks at 4°C or indefinitely at –20°C. 1 M imidazole (pH adjusted with concentrated HCl) can be filtered using 0.22-μm Millipore filter (or equivalent) and stored indefinitely at 4°C.

Digitonin stock solution, 20 mg/ml

Dissolve 20 mg/ml digitonin in water, stirring for 15 min at 90° to 95°C. Filter through 0.22-μm Millipore filter (or equivalent) and store up to several weeks at 4°C.

Digitonin is available from Merck and Sigma. Neither preparation is pure (they are contaminated mostly by other saponins that bind to cholesterol), but for purposes of the density shift experiment they can be treated as if pure. However, it is preferable not to switch brands without retitration.

Homogenization medium (lectin adsorption)

0.28 M sucrose (ultrapure; e.g., ICN Biochemicals)
50 mM 2-*N*-morpholinoethanesulfonic acid (MES), pH 6.0
150 mM NaCl
10 mM $MgCl_2$
0.1 mg/ml soybean trypsin inhibitor (Sigma)
0.1 mM phenylmethanesulfonyl fluoride (PMSF; Sigma)

PMSF has a very short half-life in aqueous solutions and must be added from a 0.2 M stock in ethanol (stored at –20°C) just before fractionation. Medium without inhibitors can be stored indefinitely at –20°C.

Pancreatic zymogen granules are labile above pH 7 and the low pH is used to keep them as intact as possible; 150 mM NaCl is included because it is reported to promote plasma membrane vesiculation with ectodomain facing outwards.

Homogenization medium (velocity differential centrifugation)

0.25 to 0.3 M sucrose (ultrapure; e.g., ICN Biochemicals)
50 mM Tris·Cl (pH 7.5; optional)
25 mM KCl (optional)

continued

BOLDRINI CENTRAL UNIVERSITY LIBRARY

5 mM $MgCl_2$ (optional)
Proteinase inhibitor cocktail (optional)

Although sucrose is the critical component of this medium, other additives are often included as well. Generally the medium is prepared fresh before use.

A suitable proteinase inhibitor cocktail includes 1 µg/ml each (final concentration in sucrose homogenization medium) of leupeptin, antipain, pepstatin, and aprotinin (some investigators also include o-phenanthroline; all available from Sigma), along with 0.2 mM AEBSF (Calbiochem) or PMSF (phenylmethanesulfonyl fluoride), in 1 mM EDTA (pH 7). These components are added from 1000× stock solutions prepared ethanol (pepstatin and PMSF) or water and stored at –20°C. PMSF has a very short half-life in aqueous solution and should be added just before starting the homogenization.

Hyperosmotic buffer

700 mM KCl
40 mM magnesium acetate
1 mM dithiothreitol (DTT)
10 mM HEPES, pH 7.5
Make fresh before use

Store DTT at –20°C as a 1 M stock solution in water.

Hypoosmotic homogenization medium (colloidal gold density shift)

15 mM KCl
1.5 mM magnesium acetate
1 mM DTT
10 mM HEPES, pH 7.5
Make fresh before use

Store DTT at –20°C as a 1 M stock solution in water.

Percoll gradient stock solutions

No-Percoll solution (low sucrose)
0.3 M sucrose
5 mM MOPS or MES buffer
1 mM EDTA
0.2 µg/ml DPPD (using 0.4 mg/ml DPPD in ethanol)
Adjust pH to 6.5-6.7 using 1 N HCl

No-Percoll solution (high sucrose)
2.15 M sucrose
35 mM MOPS or MES
7 mM EDTA

Prepare solution from the following stock solutions: 2.5 M sucrose (ultrapure; e.g., ICN Biochemicals); 1 M 2-N-morpholinoethanesulfonic acid (MES), pH 6.5; 1 M 3-N-morpholinopropanesulfonic acid (MOPS), pH 6.8; 0.2 M EDTA, pH 7.0; and 0.4 mM DPPD (diphenyl-p-phenylenediamine; Kodak) in ethanol. 2.5 M sucrose can be stored indefinitely at –20°C; 1 M MES or MOPS and 0.2 M EDTA should be filtered using 0.22-µm Millipore filter (or equivalent) and can then be stored indefinitely at 4°C; and DPPD stock should be made fresh before use.

The pK_a values of MOPS and MES are 7.2 and 6.1, respectively.

60% Percoll/sucrose: Mix 60 ml Percoll, 14 ml No-Percoll solution (high sucrose), and 26 ml water. Ajust pH as described above and add 0.2 µg/ml DPPD (from 0.4 mg/ml DPPD stock in ethanol).

86% Percoll/sucrose: Mix 86 ml Percoll and 14 ml No-Percoll solution (high sucrose). Adjust pH as described above and add 0.2 µg/ml DPPD (from 0.4 mg/ml DPPD stock in ethanol).

Percoll is slightly alkaline, so it is important to check and adjust the pH, especially if the organelles to be purified are labile at alkaline pH.

PCU IASRI CENTRAL UNIVERSITY LIBRARY

Rate zonal centrifugation gradient stock solutions

Low-density gradient solution	*High-density gradient solution*
0.5 M sucrose	1.8 M sucrose
4% (w/v) Ficoll 400	4% (w/v) Ficoll 400
5 mM MES ($pK_a = 6.1$)	5 mM MES
1 mM EDTA	1 mM EDTA
0.2 µg/ml DPPD	0.2 µg/ml DPPD

Prepare gradient solutions from the following stock solutions: 2.5 M sucrose (ultrapure; e.g., ICN Biochemicals); 50% Ficoll 400; 1 M 2-N-morpholinoethanesulfonic acid (MES), pH 6.5; 0.2 M EDTA, pH 7.0; and 0.4 mg/ml DPPD (diphenyl-p-phenylenediamine; Kodak) in ethanol. Sucrose and Ficoll stocks are stored long-term at –20°C; gradient solutions are used within two weeks of preparation; and the DPPD stock is made fresh and used without storage.

Running buffer

0.8 M sorbitol
10 mM triethanolamine
1 mM EDTA, pH adjusted to 7.2 with acetic acid (TEA)

Sorbitol is used because yeast metabolize sucrose. The running buffer generally is prepared fresh before use.

COMMENTARY

Background Information

Organelle purification procedures capitalize on the differences in size, density, and (occasionally) surface charge density of individual types of organelles. Most fractionation procedures that are based on centrifugation involve some combination of procedures that distinguish both size and density. Initially, a homogenate is prepared in isoosmotic (or slightly hyperosmotic) sucrose or some other predominantly nonelectrolyte medium. Sucrose solution deviates from ideality; while 0.3 M sucrose and 150 mM NaCl have equivalent particle concentrations, 0.25 M sucrose and 150 mM NaCl have the same osmotic activities. Investigators generally homogenize cells and tissues in solutions that are somewhere in the range of 0.25 to 0.3 M sucrose. The homogenate is filtered through cheese cloth or nylon screen to remove residual large connective tissue debris. Then differential centrifugation by velocity is used at low speed to pellet large particulates—nuclei, erythrocytes, and larger particles (including unbroken and partially disrupted cells). Subsequent treatment of the postnuclear supernatant (PNS) is a function of the mission of the experiment as discussed in the protocols.

Differential centrifugation by velocity (Basic Protocol 1) separates organelles within a cell homogenate, largely on the basis of organelle size, through successive spins of increasing centrifugal field and time in a 0.25 to 0.3 M sucrose medium. What does not sediment under the first set of conditions may sediment under one of the later sets of conditions. As all cellular organelles have a greater density than the medium, the separation is largely based on organelle size. The pellets produced during each centrifugation are enriched for organelles of a certain size but are also substantially contaminated with smaller organelles. DeDuve and Berthet (1954) calculated that in a tube where the bottom is twice as far as the surface of the liquid from the axis of rotation, a pellet containing the fastest sedimenting organelle will be contaminated by 40% of an organelle that sediments at one-third the speed and by 13% of an organelle that sediments with one-tenth the speed. Generally, further enrichment is necessary, and purity can be improved by resuspending the selected pellet in medium to its original volume and recentrifuging under the same conditions.

Although differential centrifugation by velocity is mainly used to separate and concentrate crude organelle fractions, differential centrifugation by equilibrium (Basic Protocol 2) is generally used as a follow-up to further purify organelles from contaminants according to buoyant density differences. Continuous density gradients are widely used to generate unique (but often partially overlapping) distributions along the gradient for various types of organelles within a complex mixture. The resolution is well suited for analytical purposes

POLYTECHNIC UNIVERSITY LIBRARY

where the goal is not necessarily preparative purification. In contrast, discontinuous (step) gradients are most frequently used for preparative purifications. Densities of media are selected so that the organelle of interest concentrates at the interface between particular density steps while other organelles either sediment or float to other interfaces.

An alternative to differential separation by velocity or equilibrium is rate zonal centrifugation (Alternate Protocol 1), a nonequilibrium method in which organelles separate based on a combination of size, density, and shape into enriched regions within the gradient. This method is particularly suitable for separating several types of organelles into distinct distributions within a relatively short time (1 to 3 hr rather than 8 hr to overnight as in equilibrium centrifugation). However, it should not be viewed as a substitute for differential centrifugation by equilibrium, which is one of the best ways to separate fractions of organelles of similar size but different density (e.g., rough and smooth microsomes).

Percoll-gradient fractionation (Alternate Protocol 2) has several advantages. The density gradients are isoosmotic with the homogenization medium, and due to the low viscosity, organelles approach equilibrium density quite rapidly (30 min for 1-μm organelles like granules and mitochondria; 2 hr for small (≤0.2-0.3 μm) vesicles like microsomes and endosomes). Also shallow density gradients are generated with relatively brief centrifugation; this can be advantageous for obtaining good spatial separation of organelle populations that differ only slightly in density from one another. Note, however, that because the shallow region of the gradient is bounded by regions where density changes sharply with distance in the tube (see Fig. 4.2.2), organelles with similar densities but not separated across the shallow region will tend to pile up at the boundaries. Thus Percoll is especially advantageous when the experimental goal can be reduced to separating two components from one another (or one component from the rest), and it is unlikely to be the method of choice for resolving complex mixtures into multiple subfractions that are individually enriched in different organelles. Also, it should be kept in mind that if a particular type of organelle has a heterogeneous density (e.g., endosomes), portions of the total population may be distributed on both sides of the shallow resolving segment of the gradient, depending on the concentration of Percoll selected for use.

Deuterium oxide fractionation (Alternate Protocol 3) is an equilibrium density procedure in which H_2O is partly replaced with D_2O (heavy water). It is based on the fact that the density of D_2O is 1.1 g/ml—substantially closer than that of water to the density of biological organelles. In principle, this approach should be quite useful as an aid in separating organelles, for two reasons. First, inclusion of D_2O in density gradients can significantly reduce the osmolarity of solutions that are isopycnic with most biological organelles. Second, replacement of H_2O with D_2O can reduce the density *difference* between organelles and the medium. For two populations of organelles that differ only slightly from one another in density and sediment at only slightly different rates in H_2O-based media, reducing the density difference between the organelles and the medium is one way to magnify the differences in sedimentation rate (this can be verified using the Svedberg equation—see *UNIT 4.1*). In practice, the practical value of D_2O has fallen short of expectations, mostly because the densities of several organelles increase in heavy water due to exchange of D_2O for bound water. However, such exchange may be advantageous if it occurs to differing extents between organelles and thereby magnifies their density differences. For example, Beaufay et al. (1959) showed that the buoyant density of liver mitochondria is largely unchanged in H_2O/sucrose vs. D_2O/sucrose, whereas the buoyant densities of both lysosomes and peroxisomes substantially increased in the presence of heavy water.

Both D_2O and glycerol (another popular density-modifying agent, e.g., Wagner et al., 1978) readily permeate membranes. In these media, internal and external solvents are identical. For organelles with relatively little internal solute (e.g., synaptic vesicles), sedimentation in D_2O or glycerol gradients has been quite useful in analyzing the physical characteristics of the membranes with minimized contributions from the internal solvent (Wagner et al., 1978).

Excellent fractionation procedures for a variety of cellular organelles have been described that make use of density gradient centrifugation in nonionic iodinated solutes (Alternate Protocol 4). As examples: Barlowe et al. (1994) report use of isopycnic centrifugation in Nycodenz for isolation of biosynthetically labeled, ER-derived transport vesicles from a cell-free assay; Loh et al. (1984) use metrizamide gradients in sucrose for purifying storage granules for peptide hormones from intermediate pituitary, demonstrating reasonably good

separation of granules from lysosomes; and Wattiaux et al. (1978) use metrizamide gradients to prepare highly purified lysosomes, well resolved from mitochondria and peroxisomes. The last two studies thoroughly account for a variety of marker enzyme activities.

Gel filtration (Basic Protocol 3) using controlled-pore glass (CPG-3000, Sigma; mean pore diameter 3000 Å) has been employed routinely to prepare highly purified synaptic vesicles from rat brain (Huttner et al., 1983). Sephacryl S-1000 (Pharmacia Biotech), which also excludes particles larger than 3000 to 4000 Å in diameter, has been used to purify secretory vesicles, clathrin-coated vesicles and ER-Golgi/nonclathrin-coated transport vesicles from the yeast *S. cerevisiae* (Walworth and Novick, 1987; Mueller and Branton, 1984; and Barlowe et al., 1994).

For complex mixtures of small vesicles, differences in size and density between individual types of vesicles are frequently insufficient to enable their separation as purified populations. In some of these cases, electrophoretic purification techniques—which capitalize on differences in surface charge density among the organelles—have proved useful at both the preparative and the analytical levels.

Organelle purification using preparative electrophoresis (exemplified by Basic Protocol 4) has been performed in large-porosity solid matrices such as agarose—e.g., for clathrin-coated vesicles from bovine brain and liver and from CHO cells (Rubenstein et al., 1981) and the ribonucleoprotein particles known as vaults from rat liver (Kedersha and Rome, 1986). It has also has been carried out in liquid using density gradients (which provide stability but do not contribute to the separation). The latter procedure has been used in the preparative purification of endosomes from cultured cells (Marsh et al., 1987) and secretory vesicles from *S. cerevisiae* mutants (Holcomb et al., 1987, and Basic Protocol 4). In each case, preenrichment of the samples using centrifugation techniques have been used to overcome the limitations in total protein that can be loaded.

More commonly, electrophoresis has been used at the analytical level to separate and analyze organelles that are selectively labeled by markers, as exemplified by Alternate Protocol 5. Cases where analytical electrophoresis has been applied include synaptic vesicles isolated from electric organs of marine elasmobranchs (Carlson et al., 1978) and specialized endosomes that accumulate MHC class II molecules (Amigorena et al., 1994; Tulp et al., 1994, and Alternate Protocol 5).

Both preparative electrophoresis and analytical density-gradient electrophoresis capitalize on equipment that is relatively inexpensive. In the event that a free-flow electrophoresis apparatus (e.g., Bender and Hobein Elphorvap II; cost $100,000) is available, then the procedure for its use presented in detail in Marsh et al. (1987) and subsequently employed by Amigorena et al. (1994) should be seriously considered for either preparative- or analytical-scale isolations.

Isolation of cellular organelles by solid-phase immunoadsorption using specific antibodies (Basic Protocol 5) has become very popular in the past several years. Clearly, use of these procedures requires availability of a specific antibody capable of reacting with an antigenic epitope exposed on the surface of the organelle of interest, and relies on the quality of that primary antibody and the extent to which the antigen is concentrated in the compartment of interest. These procedures can be conducted at both the preparative and analytical levels. Earlier procedures used either fixed *S. aureus* or protein A–Sepharose with adsorbed antibody (e.g., Merisko et al., 1981). This approach has continued to be used, especially for preparative-level procedures (e.g., isolation of glucose transporter vesicles; Laurie et al., 1993). As an alternative (as described in Basic Protocol 5), magnetic beads that are coated with secondary antibodies (e.g., sheep anti-mouse Fc or sheep anti-rabbit Fc) provide a new-generation solid support that allows easy isolation and is especially amenable to both functional and morphological analysis of associated organelles. The use of magnetic beads as a solid support for isolating endosomes from cultured cells and subsequently analyzing their fusion has been elegantly demonstrated by Gruenberg and Howell (1986). The properties of commercially available magnetic beads are discussed in Howell et al. (1989).

Basic Protocol 6 presents a method that uses affinity chromatography on the lectin wheat germ agglutinin (WGA) to purify apical plasma membranes from homogenates of pancreatic acinar cells (Paul et al., 1992; *UNIT 9.2*). WGA that binds both *N*-acetylglucosamine (GlcNAC) and *N*-acetyl neuraminic acid residues in glycoproteins, and interactions with WGA can be competed with free GlcNAc, which is relatively inexpensive. Other examples of lectin adsorption in subcellular frac-

BARNARD COLLEGE LIBRARY

tionation include use of WGA conjugated to iron dextran for purification of plasma membrane vesicles from CHO cells in a strong electromagnetic field (Warnock et al., 1993) and WGA–colloidal gold conjugates to remove plasma membranes prior to purification of other organelles (Gupta and Tartakoff, 1989).

A variety of density-shift techniques exist that are employed for both analytical and preparative purposes. Basic Protocol 6 presents a particularly useful density-shift strategy in which digitonin is applied to a crude organellar fraction; the compound binds to cholesterol, thereby increasing the buoyant density of different organelles to a lesser or greater extent depending on the cholesterol content of the organellar membranes. The protocol is based on the approach of Amar-Costasec et al. (1974), who applied it to a crude microsomal fraction from rat liver to demonstrate a substantial shift of marker activities of the plasma membrane (which has a high cholesterol content), a moderate density shift of a marker activity of the Golgi (which has a lower cholesterol content), and negligible shifts of markers of endoplasmic reticulum (rough microsomes) and mitochondria (which both have little or no membrane cholesterol). In turn, the density shifts of these standard markers can serve as references for comparing the behavior of proteins whose localizations are not known. A complementary procedure involving use of EDTA or pyrophosphate to strip ribosomes from the endoplasmic reticulum can be used to achieve a selective density shift of rough microsomes (Amar-Costasec et al., 1974).

Both binding to the surfaces of intact cells and endocytosis have also been used to achieve density shifts in selected organelles during subsequent fractionation. In one such procedure, receptor-mediated endocytosis of proteins conjugated to horseradish peroxidase (HRPO) has been used to label endocytic compartments which are then shifted to higher buoyant density by carrying out the cytochemical reaction of HRPO using H_2O_2 and diaminobenzidene (Courtoy et al., 1984). Unfortunately, the oxidative cytochemical reaction induces wholesale protein cross-linking within the labeled compartment, significantly limiting the potential applicability of this approach (Ajioka and Kaplan, 1987). Another interesting (though rather specialized) application used density shift by an enzyme cytochemical reaction product to distinguish clathrin-coated vesicles involved in endocytosis from other types of coated vesicles in liver (Helmy et al., 1986). On the other hand, several procedures using protein–colloidal gold (or iron-dextran) conjugates appear to offer both wider application and greater possibilities for further analysis of the isolated fractions (e.g., Warnock et al., 1993; Futter and Hopkins, 1989; Beaumelle et al., 1990; Futter et al., 1995). Among these, the use of ricin-gold, LDL-gold, and transferrin receptor antibody–gold conjugates to isolate selected compartments involved in endocytosis (Beaumelle et al., 1990) is presented as Basic Protocol 8.

Although Basic Protocol 8 is not an organelle isolation protocol, it is the procedure most widely used to extract extrinsic (or adsorbed) proteins from organelle membranes. Not only has it enabled investigators with an interest in integral membrane proteins to efficiently remove soluble contaminating proteins but it has also been used to distinguish peripheral membrane proteins (those desorbed in the presence of sodium carbonate) from integral membrane proteins (those that remain membrane-associated following treatment). As such, it is complementary to phase partitioning in Triton X-114 in which integral, but not peripheral, proteins bind the detergent and sediment in micelles at the detergent cloud point (Bordier, 1981). Note, however, that lipid-anchored (fatty acylated or prenylated) proteins either partially or fully behave as integral membrane proteins in both procedures.

Critical Parameters and Troubleshooting

These procedures can be performed using either tissue from freshly sacrificed animals (stored frozen tissues are not usually satisfactory) or cultured cells. As compared to cultured cells, however, mammalian tissues offer at least three advantages for cell fractionation and purification of various organelles. First, the cells in mammalian tissues generally are highly differentiated and, depending on the functional specialization of the selected cell type, contain large numbers of organelles per cell. Second, the mass of cells available in tissue taken even from a single rat is much larger than is readily available from reasonably large size cultures. Finally, the connective tissue matrix surrounding cells in tissues contributes to shearing during homogenization and is often an aid in efficiently disrupting cells under reasonably gentle homogenization conditions. Of the procedures discussed in *UNIT 4.1*, a glass mortar and motor-driven Teflon pestle rotating at ~1500 to 2000

rpm is used most widely for routine homogenization of tissues. If the investment of connective tissue is extensive (e.g., for parotid salivary gland) making direct homogenization with a Teflon pestle difficult, then a prehomogenization (10 sec at half-maximal power with a Tekmar Tissumizer (or Polytron) inserted directly in the glass mortar) is used before homogenization with the Teflon pestle.

The following requirements are critical for each purification method:

Differential centrifugation by velocity

The concentration of the homogenate should be standardized somewhere in the 10% to 20% (w/v) range; in especially concentrated homogenates, sedimentation properties change and aggregation is exacerbated.

The early steps of differential centrifugation by velocity may be the only chance in a multistep procedure to remove large organelles. Be sure the centrifugation is hard enough to achieve this task even if it means taking a partial loss of the desired smaller organelles. The loss can be reduced by resuspending the pellet, recentrifuging, and then pooling the second supernatant with the original supernatant.

Differential centrifugation by equilibrium

Density must be measured accurately—e.g., a refractometer should be used. In addition, reproducible preparation and collection of gradients is very important.

Upper limits to gradient loads must be identified so that organelles do not aggregate appreciably and instead continue to sediment according to their individual buoyant densities. Deceleration at the end of the centrifugation should be done with the brake in the OFF position so that gradients are minimally disturbed by mixing.

Following homogenization, vesicles deriving from a particular organelle may be heterogeneous in size and density. Further, the densities of different organelles, especially various types of small vesicles (microsomes, Golgi elements including subcompartments, and endosomes) may not differ much from one another. Thus the investigator should not expect separate, discrete bands. Rather, distributions of marker activities across the gradient must be compared.

Rate zonal centrifugation using sucrose

Reproducible preparation, loading, running, and unloading of gradients is essential. Conditions are particularly important where distributions of activities/markers are compared between tubes rather than within the same tube. Use of a refractometer to check the concentrations of solutions used to generate the density gradient is recommended. The refractometer is also useful for determining the density of gradient fractions. If a programmable centrifuge is available, use the same acceleration/deceleration program from run to run; otherwise, establish and adhere to a specific manual protocol. The separation between different organelle-enriched bands can be manipulated empirically to some extent by changing the length of centrifugation or the density limits of the gradient.

Gradient fractionation using Percoll

Because Percoll itself has negligible osmolarity, it must be added to isoomotic media. Almost all membrane-bounded organelles behave as osmometers and will lyse in hypoosmotic media. Although electrolyte-based solutions such as NaCl are generally used in separating populations of cells, organelles tend to aggregate in such media and are generally fractionated in nonelectrolyte-based media.

Close attention should be paid in preparing Percoll-sucrose mixtures so that starting densities of the self-forming gradients are reproducible. This is critical in separating organelles with very similar densities.

Because the density profile of the Percoll gradient continually changes during the run, centrifugation conditions (time and rpm) should be performed reproducibly. Centrifugation times that are too long can actually elevate the cross-contamination between low- and high-density fractions. After fractionation, it is necessary to remove the Percoll from purified fractions, as it can interfere with further processing. The simplest method to accomplish this is via additional low-speed centrifugations (as described in Alternate Protocol 2) or through ultracentrifugation on a step gradient (Zastrow and Castle, 1987).

If, instead, fractions are concentrated by high-speed centrifugation (as in several of the other protocols in this unit), Percoll will also sediment; it forms a glassy pellet and an overlying high-density gradient at the bottom of the tube. The vesicles of interest loosely congregate above the glassy pellet with the residual Percoll. Concentrating the fraction by centrifuging onto a high-concentration sucrose cushion can help because Percoll will sediment through the cushion. Alternatively, the vesicles of interest can be concentrated by flotation

BGU ILLEGRA UNIVERSITY LIBRARY

from a medium of higher buoyant density in which Percoll pellets. Finally, for SDS-PAGE of samples that contain residual Percoll, heating 5 to 10 min in sample buffer and then microcentrifuging 10 min at top speed prior to loading on the gel will remove nearly all remaining Percoll.

Gradient fractionation using D_2O

A main concern in using D_2O for fractionation is maintaining osmotic balance across organelle membranes so that lysis or leakage of contents is avoided. Gumbiner and Kelly (1981) include sucrose in their density gradient solutions to avoid lysis of secretion granules, whereas Wagner et al. (1978) include NaCl to stabilize synaptic vesicles. A similar strategy will be needed if fractionation in D_2O (or glycerol which also permeates membranes) is applied to other organelles.

Gradient fractionation using nonionic iodinated solutes

Solutions of metrizamide and Nycodenz should be stored in the dark for stability. As with other density gradient procedures, the concentrations of solutions used to prepare gradients should be standardized using a refractometer. In addition, the densities of gradient fractions collected after centrifugation can be determined by measuring refractive index.

Gel filtration

The column resin needs to be pretreated to suppress loss of small vesicles due to adsorption. This problem is particularly acute the first few times the column is used. In using controlled-pore glass (CPG-3000), Carlson and Kelly (1978) recommend treating the column periodically with polyethylene glycol (PEG; Carbowax) to suppress adsorption. The principle is the same as that used commercially in coating colloidal silica particles with polyvinylpyrrolidone in preparing Percoll. Also, pretreating the resin (either Sephacryl or CPG) by running a sample containing small phospholipid vesicles helps to suppress subsequent adsorptive losses.

Satisfactory and reproducible gel filtration of vesicles requires thorough dispersion of the starting sample. Most often this is a microsomal (small vesicle) pellet. After resuspending the pellet, it should be thoroughly dispersed by Dounce homogenization or by passage several times though a small-bore hypodermic needle (>25G). Briefly microcentrifuge the dispersed sample to pellet any residual aggregates and load the supernatant.

Preparative and analytical electrophoretic separation

To ensure that aggregation of starting material is minimal, after thorough dispersal of microsomal pellets, the samples should be microcentrifuged briefly before loading.

Setting the flow rate of the peristaltic pump used to drain the collecting well of the preparative agarose electrophoresis device for efficient clearance of separated organelles is also essential.

Solid-phase immunoadsorption

The antibody immobilized on the solid phase support must be both stably bound and active. Generally, if an antibody is good for immunoprecipitation, it is a candidate for use in immunoadsorption (contingent on epitope availability). Mouse monoclonal antibodies that have a low affinity for protein A can be adapted for immunoadsorption by using either beads coated with secondary (anti-mouse antibody) or immobilized protein A and a rabbit anti-mouse antibody bridge.

Always run a parallel control in which an irrelevant antibody is substituted for the specific antibody. This will indicate the level of nonspecific adsorption in the procedure.

Before beginning the immunoadsorption, removal of any organelle aggregates is essential. This is especially critical where centrifugation is used to collect and wash the solid phase. As in the other procedures, thorough dispersal followed by brief centrifugation can be used to eliminate aggregates (which are hopefully only a minor fraction of antigen).

For large and/or dense organelles (e.g., stacked Golgi complexes and exocrine secretion granules), it is advisable to use a plate magnet to immobilize the magnetic beads and adsorbed organelles during washing. Repeated packing of the beads by centrifugation or in the commercially available magnetic concentrator used with microcentrifuge tubes can dislodge these organelles. Furthermore, large organelles may sediment independent of their specific association with the immunoadsorbant.

Purification by lectin adsorption

Identification of a lectin that will bind to the plasma membrane of the cells of interest is essential to the procedure. Efficient elution of

PCU IASE CENTRAL UNIVERSITY LIBRARY

bound vesicles is also important; N-acetylglucosamine may not effectively compete for multiple lectin interaction sites per vesicle. An assay for a plasma membrane marker is useful to judge recovery, i.e., the amounts of membrane bound, not bound, and eluted by the competing ligand with respect to the original amount used for adsorption.

It is advisable to check marker activities for organelles that are not expected to adhere to the lectin to evaluate potential nonspecific adsorption of contaminating organelles.

Density shift using digitonin

As digitonin at higher concentrations behaves like a detergent and lyses most membrane-bounded organelles, a preliminary titration experiment is necessary to identify sublytic digitonin concentrations for use in density shift (see Basic Protocol 6, step 4).

Density shifts may be fairly subtle, especially where the cholesterol content of the membrane is low. Thus it is important to assay carefully the complete distribution of all markers and the protein (or other macromolecule) of interest across the density gradient.

Density shift using colloidal gold conjugates

In preparing colloidal gold conjugates, it is essential to identify stabilizing conditions in which the protein coating on the gold particles is sufficient to prevent flocculation. A simple test is described in the protocol.

As in most other procedures, minimal aggregation among organelles following homogenization is essential, otherwise, density perturbation extends to organelles that are associated artifactually with the particular density-modified compartment.

Extraction of extrinsic proteins from membranes using sodium carbonate

Sodium carbonate treatment is most effective if the content of other electrolytes in the sample is low. This is the reason membrane pellets are resuspended in sucrose medium with only a low buffer content and then diluted with a large volume of the high-pH carbonate solution. Carbonate induces discontinuities in the membrane bilayer (see Fujiki et al., 1982) that may be important to effectively removing extrinsic proteins. Higher concentrations of NaCl (and possibly other electrolytes) reduce the formation of discontinuities. Buffers of course decrease the pH elevation.

Do not neglect to include the sucrose cushion through which the membranes are spun after carbonate treatment. Membranes pelleted directly in carbonate are rock-like and extremely difficult to resuspend.

Anticipated Results

The key parameters to consider in judging the success of various preparative fractionation procedures are the yield of material and extent of purification. Yield is generally assessed in two ways. First, assays of organelle marker activities are used to determine what fraction of the total activity present in the original tissue homogenate is recovered in the purified fraction. This is a measure of whether the fraction is representative; generally recoveries >10% of total in the fraction of interest are satisfactory, especially as recovery is usually sacrified in the interest of purity. A complementary assessment in definitive studies involves analysis of the fractional contamination by undesirable organelles. The second measure is more practical and involves determining the amount of protein recovered in the fraction from the amount of tissue used. The extent of purification is usually judged by evaluating the enrichment of a marker activity from the homogenate to the final fraction. It is usually expressed as a ratio of activity per mg protein in the final fraction/activity per mg protein in the homogenate. For organelles that constitute large fractions of total protein—e.g., 20% for ER and mitochondria in liver (Wattiaux et al., 1978) and >25% for secretion granules in exocrine cells (Zastrow and Castle, 1987)—enrichment cannot exceed a factor of 4 or 5. However, if an organelle constitutes only 1% to 2% of total cell protein (e.g., Golgi and lysosomes in liver), then theoretical enrichments of 50- to 100-fold are possible.

For analytical procedures, the success of separations is mainly judged by the comparative distributions of marker activities for distinct organelles. Examples of anticipated results are given in Figure 4.2.1 (rate zonal centrifugation), Figure 4.2.6 (analytical electrophoresis on a density gradient), and Figure 4.2.7 (density shift using digitonin).

Examples of expected results, particularly for the preparative centrifugation techniques, are given in the following discussion. Good yields but low purity should be expected when using differential centrifugation by velocity (Basic Protocol 1). The microsomal fraction constitutes 13% of homogenate protein (18 to 20 mg protein per gram of liver used) and contains 40% to 50% of ER marker activities (glucose-6-phosphatase and ER-associated es-

BC INSTITUTE CENTRAL UNIVERSITY LIBRARY

terase), 40% of a Golgi marker (galactosyl transferase), and 25% of a plasma membrane marker activity (5′-nucleotidase; Bergeron et al., 1982). By using differential centrifugation by equilibrium (Basic Protocol 2) subsequent to differential centrifugation by velocity, rough microsomes (derived mainly from rough ER) can be efficiently purified with a yield of 7.5 to 10 mg protein per gram of liver used (Adelman et al., 1973; Bergeron et al., 1982). Mitochondria can be purified by repeated differential centrifugation by velocity (Basic Protocol 1) with a yield of 15 mg protein per gram of rat liver used (Carvalho-Guerra, 1974). Unfortunately the purity was not reported, but it would not be expected to exceed 5-fold for reasons discussed above.

Impressive purifications but often lower yields are expected using differential centrifugation by equilibrium (Basic Protocol 2) or its variations (e.g., Alternate Protocol 4). The intact Golgi fraction used as an example in Basic Protocol 2 is more than 100-fold purified from the homogenate (close to the theoretical limit, as Golgi represents close to 1% of liver protein (Wattiaux et al., 1978)). The yield of total galactosyl transferase is unusually high (33% of total); however, the absolute amount of material obtained is low (0.24 mg protein per gram liver), as expected (Bergeron et al., 1982). In isolating hepatic lysosomes using gradient centrifugation in iodinated nonionic solutes (Alternate Protocol 4), Wattiaux et al. (1978) obtained a 10% yield of lysosomal marker activities in their purest fraction and the absolute amount of protein was ~0.25 mg per gram of liver used. However, the purity of the fraction (65- to 80-fold) is extremely impressive, as lysosomes are estimated to be 1% to 1.4% of total liver protein. The procedure of Wattiaux et al. (1978) is a model for careful accounting of recovery of activities and analysis of cross-contamination of fractions by other organelles.

Yields using Percoll gradient centrifugation (Alternate Protocol 2) generally can be expected to be quite good. For the secretion granules used as an example, about 30% of the secretory protein amylase is recovered in the purified fraction. Generally 20% to 25% of amylase is released from granules that lyse during homogenization, while another 20% fails to be released from cells during homogenization; the latter sediments in the nuclear pellet (see Zastrow and Castle, 1987, and references therein). For secretion granules, which are much more dense than other cytoplasmic organelles, the purity of fractions obtained using Percoll gradients can be expected to be quite good, provided conditions of centrifugation (Percoll density, times of runs) are used reproducibly. Where organelles of interest and contaminants have more similar densities, the possibility of contamination can be significant and needs to be considered. Even though the forte of Percoll is generating very shallow density gradients with good spatial resolution, biological organelles are heterogeneous (either intrinsically or especially after cell homogenization) and distribution of a particular organelle over a range of densities can be expected.

Gel filtration to isolate secretory vesicles (Basic Protocol 3) is a procedure that is restricted to small organelles. Losses due to vesicle adsorption to the column matrix can be expected to be significant (possibly as much as 50%) during initial use of the column but should improve significantly thereafter. Even though vesicle purification using the column can be impressive, homogeneity should not be expected. Homogenization generates small vesicles from larger organelles and these will co-fractionate with the secretory (or synaptic) vesicles. Generally it is wise to follow the distribution of marker activities in the fractions eluted from the column (as in Fig. 4.2.3) if co-localization is being evaluated.

The use of electrophoretic techniques (e.g., Basic Protocol 4 and Alternate Protocol 5), although quite promising, is still rather limited. The initial efforts suggest that both recovery and purity using the preparative procedure may be quite high for selected organelles (Kedersha and Rome, 1986). However, more widespread use is needed before it is possible to establish expectations for yield and purity. Lectin-based purification of plasma membrane fractions (Alternate Protocol 6) also has not been employed both widely and quantitatively. For the exocrine pancreatic apical plasma membrane fraction used as an example, yields were not reported. However, the fact that most plasma membrane vesicles are oriented with ectodomain outward (and thus accessible to the lectin) suggests that the yield could potentially be good. The purification (75-fold enrichment over the homogenate) is very good (Paul et al., 1992).

Density-shift using colloidal gold conjugates (Basic Protocol 7) appears to be quite promising for obtaining fractions enriched in different segments of the endocytic pathway in both quite good yield and purity (Beaumelle et al., 1990). The yields reported for plasma membranes, endosomes, coated pits, and lysosomes

isolated by density modification are 40%, 32%, 10%, and 16%, respectively. Contamination by organelles outside the endocytic pathway appears negligible based on marker assays. Cross-contamination among endocytic compartments also appears to be low but potentially is limited by the extent to which individual compartments can be density-modified selectively in the cells prior to fractionation.

Extraction of extrinsic proteins from membranes using sodium carbonate (Basic Protocol 8) generally can be expected to be 90%, while retention of integral proteins in sedimentable membranes is usually quantitative. A result suggesting partial extraction will be difficult to interpret. If established integral membrane proteins are underrecovered the final membrane pellets, then incomplete recovery of membranes following centrifugation needs to be considered. On the other hand, if the loss of the proteins of interest is selective with respect to the markers, then these proteins may be extrinsic but inefficiently extracted. In this case, distribution should be judged following a repeat extraction.

Time Considerations

This section provides estimates of the time required for organelle purification by the procedures that are likely to be used most frequently. For the other protocols, total times and convenient breakpoints can be easily estimated from the steps that are listed.

In differential centrifugation by velocity (Basic Protocol 1), sample preparation and homogenization takes about 20 min; centrifugation to obtain the PNS takes 10 min; ultracentrifugation to obtain the crude mitochondrial fraction requires 30 min, and further purification takes another 30 min; finally, ultracentrifugation to obtain the microsomal pellet requires 2 hr. For each step requiring resuspension of pellets, include an additional 10 min.

In differential centrifugation by equilibrium (Basic Protocol 2), preparation of the density gradients requires 30 to 60 min in advance of starting the fractionation. Sample preparation and homogenization takes about 20 min while loading the gradients takes about 15 to 30 min depending on experience. Running the gradient takes 3 hr (with an additional 15 to 30 min to allow the rotor to coast to a stop) in the example given; however, in most equilibrium runs this step goes overnight. Allow ~30 min to collect the bands from the gradients after the run, 90 min to pellet them by additional centrifugation, and 15 min to resuspend them for use or storage. In many procedures, the gradient step is used in series with differential centrifugation by velocity, so selected times as in Basic Protocol 1 need to be added in.

In rate zonal centrifugation (Alternate Protocol 1), preparation of the gradients requires 30 to 60 min in advance of starting the fractionation. Sample preparation and homogenization takes 20 to 30 min (more time is allotted for surgery to remove pancreas, which is more difficult than for liver); low-speed centrifugations to prepare the PNS require 30 min together; loading gradients takes 15 to 30 min; gradient centrifugation requires 2 hr plus a 30-min coast of the rotor to stop; and collection of the fractionations either manually or with a gradient-elution device requires 10 to 15 min per centrifuge tube. Any additional centrifugation to pellet fractions generally requires 1 to 1.5 hr, with 15 min to resuspend pellets at the end.

For gradient fractionation using Percoll (Alternate Protocol 2), allow 60 min for sample preparation, homogenization, and generation of PNS as above. Any adjustment of density requiring measurement of refractive index takes ~10 min, while centrifugation of the gradients requires 30 min to 2 hr, depending on the organelle being isolated. Collection of fractions after the run requires 5 or 15 min per centrifuge tube for manual collection or collection with a gradient-elution device, respectively. Subsequent centrifugation to separate most of the Percoll from the fractions requires 45 min in a low-speed centrifuge or 1 to 2 hr if sedimentation in an ultracentrifuge is used.

Gradient fractionation using nonionic iodinated solutes (Alternate Protocol 4) requires similar amounts of time as above for sample preparation, homogenization, and centrifugation to generate a PNS. In the example protocol given, the rehomogenization and recentrifugation of the initial nuclear pellet adds another 20 min to give a total time of ~60 min to prepare the PNS for loading on gradients. A 10,000-rpm centrifugation to pellet mitochondria requires an additional 30 min. Continuous gradients can be made in advance of starting the experiment whereas discontinuous gradients are usually made right before use during the low-speed centrifugation steps; allow 10 min per tube. Ultracentrifugation of the gradients requires 2.5 to 3 hr (including coast of the rotor to a stop). Unloading gradients takes 10 to 15 min per tube. Any additional centrifugation to pellet

BOURNEMOUTH UNIVERSITY LIBRARY

the isolated fractions requires 1.5 hr plus 5 min per tube to resuspend the final pellets for assays or storage.

For gel filtration (Basic Protocol 3), sample preparation and centrifugation to prepare the column load approximately follows the time-course for differential centrifugation by velocity. Where yeast are used as a source of sample, allow 60 min to spheroplast and harvest the yeast by centrifugation before starting the homogenization. The gel-filtration column is run overnight; fractions are maintained at 4°C during assay, and then an additional 1 to 1.5 hr is needed for pooling the selected fractions and pelleting them by centrifugation.

For electrophoretic separations (Basic Protocol 4 and Alternate Protocol 5), about 3 to 4 hr is required for preparing and homogenizing tissue and sedimenting the microsomal starting material for the electrophoretic separation. Centrifugation times are similar to those in Basic Protocol 1, and additional time is included to allow for assay of total protein and brief trypsinization (Alternate Protocol 5). The agarose gel for preparative electrophoresis (Basic Protocol 4) can be prepared in advance of the experiment and requires at least 2 hr to solidify before use. The density gradient for analytical electrophoresis (Alternate Protocol 5) requires ~30 min and is set up just before loading. Preparative electrophoresis in agarose is conducted for 16 hr, while analytical electrophoresis on the density gradient will take an hour, including the solution changes during the run. Fractions for assay and further processing are collected continuously during electrophoresis on the agarose gel whereas fractions are collected at the end of the run on the analytical density gradient, requiring 30 min.

Solid-phase immunoadsorption using antibody-coated magnetic beads (Basic Protocol 5) requires 4 hr overnight incubation in advance of the experiment to coat the beads with antibody and subsequently wash them. During the experiment, preparation of the PNS requires about 30 min (as in Basic Protocol 1). Subsequent centrifugation to prepare membranes to load on the gradient requires 1.5 hr (including loading and unloading the tubes) in the example given. Preparation and loading of discontinuous gradients, centrifugation, and collection of fractions requires a total of 2 to 2.5 hr. Immunoadsorption of organelles requires 3 hr and subsequent washing needs another 30 min before samples are harvested or used in functional assays.

Extraction of extrinsic proteins from membranes using sodium carbonate (Basic Protocol 8) can be performed either immediately after preparation by any of the protocols listed or after storage of samples that have been resuspended in buffered sucrose and frozen. Carbonate treatment requires 30 min; loading of treated samples for pelleting through a sucrose cushion requires 5 min per centrifuge tube; and centrifugation requires 1 to 2 hr. Collecting the final supernatants and resuspended pellets requires 5 min per tube.

Subcellular Fractionation of Tissue Culture Cells

The development of cell fractionation techniques over the last few decades has provided the means to analyze the composition and properties of purified cellular elements. In particular, subcellular fractionation is essential for the development of cell-free assays that reconstitute complicated cellular processes. These assays have provided new and important tools to understand the molecular mechanisms of complex cellular functions permitting these functions to be studied in the test tube as a series of biochemical reactions.

General methods for fractionating mammalian tissues are presented in *UNIT 4.2*. The protocols in this unit describe fractionation of tissue culture cells to immunoisolate early and late endosomes under conditions where these compartments retain their capacity to support membrane transport in vitro. To prepare different populations of endosomes, monolayers of cells are exposed to a fluid-phase marker for endosomal compartments (horseradish peroxidase, HRPO) either briefly to label early endosomes or with a chase period to label endosomal carrier vesicles or late endosomes (see Basic Protocol 1). Alternatively, vesicular stomatitis virus (VSV) can be fused with the cells to add VSV G protein to the cell membranes (see Basic Protocol 2) and the cells then exposed to HRPO. Labeled cells from either protocol are then homogenized (see Basic Protocol 3) and the postnuclear supernatant (PNS) is fractionated by a flotation gradient (see Basic Protocol 4). Specific endosomal compartments are isolated using magnetic or polyacrylamide beads coupled to an antibody specific for VSV G protein (see Basic Protocol 5). The Support Protocol describes growth conditions for preparing BHK-21 cells for isolation of endosomes. The Commentary discusses preparation of a "balance sheet" for the isolation procedure (see Background Information) and problems that may be encountered in subcellular fractionation of tissue culture cells (see Critical Parameters as well as the Commentary in *UNIT 4.2*).

INTERNALIZATION OF FLUID-PHASE MARKER

BASIC PROTOCOL 1

Several proteins, including rab GTPases and receptors (see Table 4.3.1), can be used to follow early or late endosomes. In the absence of appropriate reagents, markers endocytosed in the fluid phase can allow convenient discrimination between the compartments (see Table 4.3.1). Horseradish peroxidase (HRPO) is widely used as a marker for fluid-phase endocytosis. HRPO internalized at a concentration of 0.5 to 10 mg/ml distributes uniformly within the lumen of endosomal compartments and is easily measured using a colorimetric reaction. Internalization is carried out directly in the tissue culture dish for cells growing attached to the substratum. For suspension cells, the method is essentially identical, except that all changes of buffers and solutions must be accomplished by centrifugation. Once labeled, the cells must be washed thoroughly to remove nonspecifically adsorbed marker. Washed cells may be incubated further in the absence of marker to label endosomal carrier vesicles and late endosomes.

Materials

Monolayer cultures of BHK-21 cells in 10-cm tissue culture plates, 14 to 18 hr after plating (see Support Protocol 3)
PBS (*APPENDIX 2E*), ice cold
2 to 10 mg/ml horseradish peroxidase (HRPO) in internalization medium (see recipe), 37°C
PBS/BSA: PBS containing 5 mg/ml BSA, ice cold and 37°C
IM/BSA: Internalization medium (see recipe) containing 2 mg/ml BSA, 37°C

BOSTON COLLEGE CENTRAL UNIVERSITY LIBRARY

Table 4.3.1 Labeling Conditions for Characterization of the Different Endosomal Compartments[a,b]

Endosomal compartment	Duration of incubation at 37°C	Markers	References
EE	5 min	Rab5, rab4	Chavrier et al. (1990); Gorvel et al. (1991)
		Annexin II	Emans et al. (1993)
		Receptors recycling with the plasma membrane (e.g., transferrin-R)	Gruenberg and Howell (1989); Emans et al. (1991)
ECV	5-min pulse + 45-min chase after depolymerization of microtubules		Gruenberg et al. (1989); Bomsel et al. (1990); Aniento et al. (1993)
LE	5-min pulse + 45-min chase	Rab7, rab9	Chavrier et al. (1990); Gorvel et al. (1991)
		CI-MPR	Griffiths et al. (1988); Aniento et al. (1993a)
		lgps	Geuze et al. (1983); Griffiths et al. (1988); Gorvel et al. (1991)

[a]Several proteins listed here exhibit a restricted distribution within endosomes, but can also be found in other compartments (e.g., MPR in TGN and late endosomes; rab5 in plasma membrane and early endosomes). Analysis of purified fractions must thus combine different markers to identify endosomes unambiguously.

[b]Abbreviations: transferrin-R transferrin receptor; CI-MPR, cation-independent mannose-6-phosphate receptor; lgps, lysosomal glycoproteins; TGN, trans Golgi network. The 4a1 and 2a5 monoclonal antibodies recognize two lgps that are abundant in late endosomes (Aniento et al., 1993).

Cold plate: wet metal plate lying flat on top of ice in an ice bucket
Rocking platform
Warm plate: 37 °C water bath with a flat metal plate slightly below the water level
or 37°C incubator

1. Place tissue culture dishes containing monolayer cultures of BHK-21 cells on the cold plate. Aspirate the medium and add 5 to 10 ml ice-cold PBS to each dish. Incubate 2 to 3 min on a rocking platform. Repeat this step twice to thoroughly wash the cells.

   Use two to three dishes of cells per time point. Keep the dishes level on the plate in the ice bucket.

2. Aspirate the PBS and prewarm each dish 1 to 2 sec on the warm plate. Add 2.5 ml prewarmed HRPO to the dish and incubate 5 min on the warm plate.

   In most cases, HRPO at a concentration of 2 mg/ml provides sufficient labeling. If necessary, higher concentrations (up to 10 mg/ml) can be used to increase the signal (for example, when fractions are further purified by immunoisolation).

   To reduce costs, small volumes of HRPO (e.g., 2.5 ml) can be used for incubation at 37°C. The culture dish should be placed on a metal plate mounted on a rocking platform in a 37°C incubator to ensure that the cells are adequately covered with liquid during the incubation.

   After a 5-min incubation at 37°C, membrane proteins and fluid-phase tracers distribute predominantly within early endosomes (Gruenberg et al., 1989; Gorvel et al., 1991; Emans et al., 1993). After longer internalization times, the markers appear first in endosomal carrier vesicles and then sequentially in late endosomes and lysosomes (Bomsel et al., 1990; Aniento et al., 1993a).

3. Return the dishes to the cold plate. Aspirate the HRPO and wash each dish three times, 5 to 10 min each, with 5 ml PBS/BSA. Aspirate the PBS/BSA and wash each dish

PCU IASI / CENTRAL UNIVERSITY LIBRARY

twice with 5 ml PBS. To label endosomal carrier vesicles or late endosomes, proceed to steps 4 and 5. Otherwise, proceed to homogenization (see Basic Protocol 3).

4. *Optional:* If the experiment requires fluid-phase labeling of endosomal carrier vesicles or late endosomes, immediately after the internalization step rinse each dish two or three times with 5 ml of 37°C PBS/BSA. Add 10 ml IM/BSA and incubate 45 min at 37°C.

   These pulse-chase conditions are preferred to continuous internalization of HRPO because under these conditions the amount of HRPO in earlier compartments is reduced.

5. Return the dishes to the cold plate. Then, as in step 3 above, aspirate the medium and wash each dish twice, 5 min each, with 5 ml PBS/BSA. Aspirate the PBS/BSA and rinse twice with PBS.

   Markers can also be allowed to accumulate in the intermediate endosomal carrier vesicles by preincubating the cells 1 to 2 hr at 37°C in medium containing 10 μM nocodazole to depolymerize microtubules. The conditions for fluid-phase labeling and marker internalization are the same, except that all wash solutions and media used, including internalization and chase media, should contain 10 μM nocodazole. Alternatively, endosomal carrier vesicles can be labeled by incubating the cells 2 hr at 20°C without nocodazole. However, internalization rates and labeling efficiency will be higher at 37°C than at 20°C.

IMPLANTATION AND INTERNALIZATION OF VSV G PROTEIN

BASIC PROTOCOL 2

The transmembrane glycoprotein G of vesicular stomatitis virus (VSV), or another transmembrane endosomal antigen for which there is an antibody, can be used to immunoisolate endosomal fractions (see Fig. 4.3.1). Virus is first bound to the plasma membrane by wheat germ agglutinin–mediated adhesion, then fused with the plasma membrane by a brief exposure to low pH medium that inhibits endocytosis (Davoust et al., 1987). The cells are then washed and incubated with HRPO at 37°C. Under these conditions, the G protein, a membrane marker, is co-internalized with HRPO, a fluid-phase marker. The G protein cytoplasmic domain becomes exposed on the surface of endosomal elements and is accessible to antibodies after homogenization.

Materials

Monolayer cultures of BHK-21 cells in 10-cm tissue culture plates, 14 to 18 hr after plating (see Support Protocol 3)
100 μg/ml wheat germ agglutinin (WGA) from *Triticum vulgaris* (Sigma) in 7.4 M medium (see recipe), ice cold
20 μg/ml vesicular stomatitis virus (VSV; see Support Protocol 1) in 7.4 M medium (see recipe), ice cold
Fusion medium: MEM containing 20 mM succinate, pH 4.9, 37°C
60 mM *N*-acetylglucosamine (GlcNAc) in 7.4 M medium (see recipe), ice cold
Vacuum aspirator connected to a trap containing disinfectant (e.g., chloramine T)
Additional reagents and equipment for fluid-phase internalization (see Basic Protocol 1)

CAUTION: VSV is a rodent pathogen. Consult with the local hazardous materials authority for proper handling and disposal procedures. All plastic, glassware, and solutions can be disinfected with chloramine T.

BOSTON BIOMEDICAL RESEARCH INSTITUTE LIBRARY

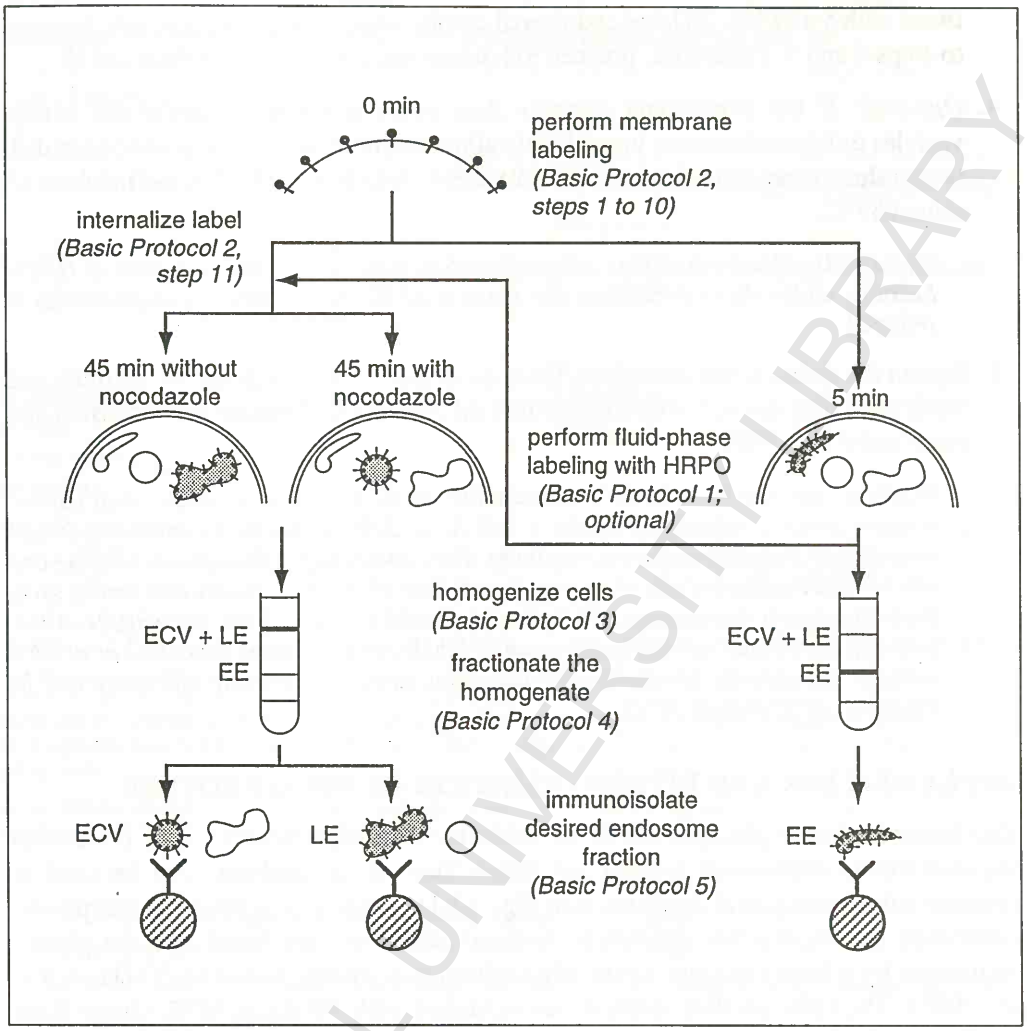

Figure 4.3.1 Outline of the complete procedure followed for the immunoisolation of early endosomes (EE), endosomal carrier vesicles (ECV), and late endosomes (LE). The G protein of the VSV virus is implanted into the plasma membrane by low pH–mediated fusion of the virus with the plasma membrane. Then, G protein molecules are cointernalized with horseradish peroxidase (HRPO) to introduce the G protein into EE, ECV, or LE, respectively. The cells are then homogenized and the PNS is prepared. The PNS is fractionated on a flotation gradient. The EE fraction or the ECV/LE fractions are used as input for immunoisolation using beads coupled to an antibody against the G protein cytoplasmic domain. Depending on the internalization conditions for the G protein, ECV can be separated from LE.

Wash the cells

1. Chill monolayer cultures of BHK-21 cells on the cold plate. Place the cold plate on a rocking platform.

   The dishes must lie perfectly flat on the plate. A rocking platform should be used for all incubations, particularly those with small volumes (e.g., <5 ml).

2. Rapidly aspirate the medium and rinse twice with 5 ml ice-cold PBS to ensure proper chilling of cells and removal of cellular debris.

Bind WGA to cells

3. Aspirate the PBS and add 2.5 ml ice-cold WGA. Incubate 1 hr on the cold plate.
4. Aspirate the medium and wash twice with 5 ml PBS.

ECU IASI CENTRAL UNIVERSITY LIBRARY

Bind VSV to cells

5. Aspirate the PBS and add 2.5 ml ice-cold VSV. Incubate 1 hr on the cold plate.

   Addition of 50 μg VSV protein to a 10-cm dish of confluent BHK-21 cells results in the fusion of 8.5 μg VSV protein with the plasma membrane; this corresponds to ~80 molecules of VSV G protein/μm² membrane surface area (Gruenberg and Howell, 1987).

6. Aspirate the virus solution and wash the cells twice with 5 ml PBS.

7. Remove the dish from the cold plate, aspirate the wash solution, and add 20 ml of 37°C fusion medium. Incubate 30 sec at 37°C.

   Low pH–mediated fusion at 37°C results in the incorporation of G protein molecules in the correct transmembrane orientation. Because all steps except the fusion are done on ice and because endocytosis is arrested at pH 4.9, G protein is restricted to the plasma membrane.

8. Aspirate the fusion medium and quickly place the dish back on the cold plate. Rinse twice with 5 ml ice-cold PBS.

Remove unfused VSV

9. Remove unfused virions by aspirating the PBS, then adding 5 ml of ice-cold 60 mM GlcNAc. Incubate 1 hr on the cold plate.

10. Aspirate the GlcNAc and wash twice with PBS.

Internalize G protein

11. Add 10 ml IM/BSA and incubate 5 min *or* 45 min at 37°C.

    After 5 min, G protein is found predominantly in early endosomes; after 45 min, it is found primarily in late endosomes. Endosomal carrier vesicles contain the G protein after 45 min if microtubules are depolymerized by treatment with nocodazole (see Basic Protocol 1).

12. *Optional:* If a general marker for endosomes is required, e.g., to establish a balance sheet for fractionation, cointernalize HRPO with the G protein (see Basic Protocol 1).

PREPARATION OF VSV STOCKS

SUPPORT PROTOCOL 1

For this immunoisolation experiment, the antigen is provided by the cytoplasmic domain of the transmembrane glycoprotein G of the enveloped virus, vesicular stomatitis virus (VSV). VSV stocks are produced and harvested as described in Gruenberg et al. (1989). Briefly, subconfluent 2-day cultures of BHK cells are infected with 0.2 pfu VSV/cell and incubated 19 to 20 hr at 37°C. Medium containing virus is removed from the cells and centrifuged 30 min at $7000 \times g_{avg}$ in an HS4 rotor to remove cell debris. The supernatant is layered on top of a two-step gradient of 10% and 55% (w/v) sucrose in 50 mM Tris·Cl/100 mM NaCl/0.5 mM EDTA (pH 7.4) and centrifuged 90 min at $90,000 \times g_{avg}$. Virions are collected at the 10%/55% interface. Aliquots of 50 and 200 μg are frozen in liquid nitrogen and stored at –70°C.

BCU IAS CENTRAL UNIVERSITY LIBRARY

BASIC PROTOCOL 3

HOMOGENIZATION OF TISSUE CULTURE CELLS

Gentle homogenization conditions should be used to limit possible damage to endosomal elements, particularly when using fluid-phase markers. Clearly, the markers should remain entrapped in vesicles (latent) after homogenization. In addition, harsh conditions should always be avoided to limit the breakage of lysosomes and consequent proteolysis by released hydrolases. Cells grown for 14 to 16 hr are easily homogenized, so each step of the homogenization process should be monitored using a phase-contrast microscope. A balance sheet should be used to follow the distribution of protein and markers during homogenization, flotation, and immunoisolation (see Table 4.3.2 for an example). Labeled cells are scraped from the dish, homogenized, and centrifuged to prepare a PNS.

Materials

Monolayer cultures of BHK-21 cells labeled with VSV G protein and/or fluid-phase marker (see Basic Protocol 1 or Basic Protocol 2)
PBS (*APPENDIX 2E*), 4°C
Homogenization buffer (HB; see recipe)
Protease inhibitor cocktail (see recipe)

15-ml plastic conical centrifuge tube
Refrigerated centrifuge and rotor appropriate for cell sedimentation
22-G needle attached to a 1-ml syringe
Phase-contrast microscope
Beckman Airfuge or equivalent ultracentrifuge

Additional reagents and equipment for assay of horseradish peroxidase activity (Support Protocol 2)

Collect cells

1. Remove cells from the dish by scraping with a rubber policeman in 2.5 ml of 4°C PBS and transfer to a 15-ml plastic conical centrifuge tube. Centrifuge 5 min at 700 × *g*, 4°C.

   Typically, the contents of three to five dishes are pooled into a 15-ml tube.

2. Remove and save the supernatant. Resuspend cell pellet very gently in 5 ml homogenization buffer using a wide-bore pipet. Centrifuge 10 min at 1500 × *g*, 4°C.

3. Analyze the supernatant for the presence of markers due to cell breakage during removal from the plate.

   Cell breakage during removal should not exceed 5% to 10%.

Homogenize cells

4. Add 0.5 ml protease inhibitor cocktail in HB to the cell pellet and resuspend using a 1000-µl pipettor with a blue (1000-µl) tip.

   Homogenization is easier at a relative high cell density, e,g, 20% to 30% (v/v).

   Cells grown in suspension or that are released from the dish by trypsin treatment may require harsher homogenization conditions. The use of a tight-fitting glass-glass Dounce homogenizer (15 to 20 passages of the pestle) or a "cell cracker" may be required to achieve good cell breakage. A cell cracker is a device used to pass cells through a precision clearance between the wall of a metal chamber and a metal ball bearing (Balch and Rothman, 1985).

5. Draw the homogenate three to ten times through a 22-G needle attached to a 1-ml syringe. Monitor homogenization using a phase-contrast microscope. Be careful not to over-homogenize.

PCU IASI CENTRAL UNIVERSITY LIBRARY

Nuclei should be intact and free of cellular materials.

Damage to endosomes and lysosomes can be quantified by measuring the latency of content markers, lysosomal enzymes, or other integral markers (latency corresponds to the percentage of a marker that remains entrapped within vesicles—e.g., endosomes) after homogenization. Under optimal conditions, latency should be >75% after homogenization.

6. Centrifuge the homogenate 15 min at 1500 × *g*, 4°C and collect the PNS and the nuclear pellet (NP). Resuspend the nuclear pellet in 1 ml PBS. Save a 50-µl aliquot of the PNS and the nuclear pellet for analysis.

   The PNS is ready for fractionation.

Determine latency of markers

7. Dilute a 20-µl aliquot of the PNS with HB to a total volume of 0.2 to 1 ml, depending on the amount of PNS necessary to detect the marker.
8. Centrifuge 15 min at 200,000 × *g* (e.g., 20 psi in a Beckman Airfuge), 4°C.
9. Collect the supernatant. Resuspend the pellet in the same volume of HB as used in step 7.
10. Determine the amount of HRPO or other marker in the original PNS, in the pellet, and in the supernatant (see Support Protocol 2).
11. Calculate the amount of marker in the pellet as a percentage of the total amount present in the PNS (yield).

DETERMINATION OF HORSERADISH PEROXIDASE ACTIVITY

SUPPORT PROTOCOL 2

Internalized HRPO is measured using *o*-dianisidine and peroxide as substrates; the brown-colored product is quantitated by measuring the absorbance at 455 nm with a spectrophotometer.

Materials

Subcellular fraction containing internalized HRPO (see Basic Protocol 3)
HRPO substrate solution (see recipe)
HRPO standards: 10 to 100 ng HRPO/ml in the same buffer used to prepare or dilute sample
10 µM potassium cyanide (KCN; optional)

1. Quickly mix 0.1 ml of sample with 0.9 ml substrate solution. Mix 0.1 ml of each HRPO standard with 0.9 ml substrate solution. Incubate at room temperature in the dark. Time the reaction.

   If necessary, sample may be diluted with PBS (APPENDIX 2E) or other buffer before analyzing an 0.1-ml aliquot.

2. When a brown color develops, note the time and measure the absorbance of sample and standards at 455 nm.

   With small amounts of HRPO, the reaction can be developed for up to 2 hr in the dark. It is not necessary to stop the reaction, but the heme group of HRPO can be blocked at the desired time by adding a respiratory inhibitor such as 10 µm KCN.

3. Use the values obtained for HRPO standards to quantitate the amount of HRPO in the sample.

BCU IAS / CENTRAL UNIVERSITY LIBRARY

BASIC PROTOCOL 4

FLOTATION-GRADIENT FRACTIONATION OF TISSUE CULTURE HOMOGENATES

Early and late endosomal fractions can easily be prepared from postnuclear supernatants (PNS) by flotation in a step gradient of 40.6% to 8.6% (w/w) sucrose/D_2O. Early endosomes containing the transferrin receptor, the small GTPase rab5 protein, and annexin II can be separated from late endosomes containing the rab7 protein, lysosomal glycoproteins (lgps), and the cation-independent mannose-6-phosphate receptor (see Table 4.3.1). Fractions from this gradient can be used to determine the general protein composition of the fractions in high-resolution two-dimensional gels (*UNIT 10.4*) and to reconstitute the different endosomal membrane fusion events (see Fig. 4.3.2).

Materials

Postnuclear supernatant (PNS; see Basic Protocol 3)
Sucrose solutions (see recipes)
Homogenization buffer (HB): 250 mM sucrose/3 mM imidazole

Refractometer
SW60 centrifuge tubes
Ultracentrifuge and SW60 rotor
Peristaltic pump connected to a 50-µl capillary tube

1. Dilute the PNS 1:1 (v/v) with 62% sucrose solution in H_2O to give a solution of 40.6% sucrose/0.5 mM EDTA and check the final sucrose concentration with a refractometer.

2. Load 1 ml of the diluted PNS in the bottom of an SW 60 centrifuge tube and overlay sequentially with 1.5 ml of 16% sucrose solution in D_2O, then 1 ml of 10% sucrose solution in D_2O. Add HB to fill the tube.

   Early and late endosomes can also be isolated on a gradient with 35% and 25% sucrose solutions in H_2O. Also, the low-density sucrose step (10% in D_2O or 25% in H_2O) can be omitted to yield fractions containing mixed populations of early and late endosomes.

3. Mount the tubes in an SW60 rotor and centrifuge 1 hr at 14,000 × g_{avg} (35,000 rpm), 4°C.

4. In a 4°C cold room, use a peristaltic pump connected to a 50-µl capillary tube to collect the gradient.

   The early endosome fraction containing the transferrin receptor, the small GTPase rab5, and annexin II is collected from the 16%/10% interface (or 35%/25% interface). The late endosome fraction containing the rab7 protein, lysosomal glycoproteins

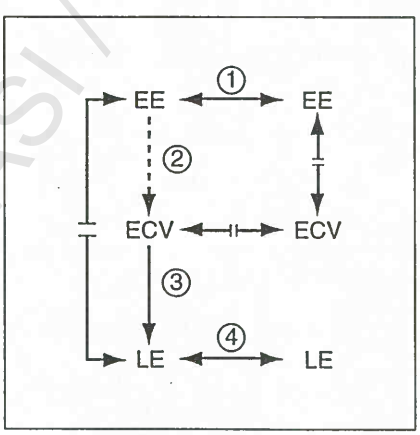

Figure 4.3.2 Outline of the different endosome fusion events reconstituted in an in vitro fusion assay. EE undergo homotypic fusion with each other (1; Gruenberg and Howell, 1989). Several components regulating this process have been identified (Gruenberg and Clague, 1992). ECV form from EE (2) in a process that requires vacuolar ATPase activity (Clague et al., 1994). ECV fuse with LE (3) in a process facilitated by microtubules and cytoplasmic dynein (Aniento et al., 1993a). LE also undergo homotypic fusion with each other (4). All other combinations (EE-ECV, ECV-ECV, and EE-LE) are refractory to fusion (Aniento et al., 1993a). Abbreviations: ECV, endosomal carrier vesicles; EE, early endosomes; LE, late endosomes.

ECU IASI / CENTRAL UNIVERSITY LIBRARY

(lgps), and the cation-dependent mannose-6-phosphate receptor (CI-MPR) is collected from the upper portion of the 10% cushion (or 25% cushion in H_2O).

5. Divide early and late endosome fractions into 50-µl aliquots, then freeze and store them in liquid nitrogen.

   Aliquots should be placed in a liquid nitrogen bath for rapid freezing; similarly, they should be thawed as rapidly as possible prior to use or analysis.

IMMUNOISOLATION OF ENDOSOMAL FRACTIONS

BASIC PROTOCOL 5

Immunoisolation can be used to purify any subcellular fraction as long as a specific antibody is available. The specific antibody is coupled to magnetic or polyacrylamide beads with a covalently coupled species-specific linker antibody, then the beads are used to precipitate the desired organelle. A similar strategy has been used to immunoisolate other organelles with different antigen/antibody couples (Morré et al., 1988; Howell et al., 1989a). The procedure for immunoisolating endosomes using VSV G protein as the antigen is described here.

Materials

Rabbit anti-mouse immunoglobulin covalently coupled to polyacrylamide or magnetic beads (e.g., Immunobeads, Bio-Rad)
PBS/BSA: PBS (*APPENDIX 2E*) containing 2 mg/ml BSA, ice cold
Mouse antibody against the cytoplasmic domain of VSV G protein (P5D4; Kreis, 1986)
Endosomal fractions (see Basic Protocol 4)
Microcentrifuge, refrigerated
Low-speed rotating wheel (2 to 20 rpm)

1. Resuspend 1 to 10 mg rabbit anti-mouse immunoglobulin covalently coupled to polyacrylamide or magnetic beads in 1 ml PBS/BSA and microcentrifuge 2 to 3 min at 3000 × *g*, 4°C.

   Immunobeads are also available with antibodies to immunoglobulins from other species.

2. Wash the beads four times with PBS/BSA by centrifugation as in step 1.

3. Add 5 to 10 µg mouse anti–G protein antibody/mg bead in a total volume of 1 ml PBS/BSA for 1 to 10 mg of beads. Rotate end over end overnight at 4°C.

4. Remove excess antibody by washing three times with PBS/BSA. Resuspend the beads at 10 mg/ml in PBS/BSA.

5. Dilute the endosome fraction 1:3 with ice-cold PBS/BSA in a 1.5-ml microcentrifuge tube to a final volume ~1 ml.

6. Add 1 mg beads with bound antibodies to the cellular fraction. Rotate end over end 2 hr at 4°C.

   For either polyacrylamide or magnetic beads, 1 mg solid support (a pellet of ~20 µl) is used for immunoisolation from 300 to 500 µg PNS protein or 50 µg protein of a fraction collected from the gradient (the equivalent of cells from 10 to 20 cm^2 of tissue culture surface area).

7. Centrifuge the beads/fraction mixture 5 min at 3000 × *g* in a refrigerated centrifuge. Collect the supernatant for analysis. Gently resuspend the pellet in 1 ml PBS/BSA to prevent vesicularization and repeat the centrifugation.

B.C.U. „M. Kogălniceanu" IAŞI
CHIMIE

BCU IASI / CENTRAL UNIVERSITY LIBRARY

If the sample is to be analyzed by gel electrophoresis, the last wash should be in PBS without BSA.

The amount of immunoisolated protein cannot be quantitated directly because of the added BSA and antibodies. However, it is possible to obtain an estimate by using cells metabolically labeled with [^{35}S]methionine.

8. Resuspend the beads plus bound vesicles in 100 µl medium or buffer.

The choice of medium or buffer depends on how the sample will be analyzed; for example, use homogenization buffer (see recipe) for a cell-free assay of endosome fusion (Gorvel et al., 1991; Aniento et al., 1993a) or lysis buffer for two-dimensional gel electrophoresis (UNIT 10.4).

SUPPORT PROTOCOL 3

PREPARATION OF TISSUE CULTURE CELLS FOR SUBCELLULAR FRACTIONATION

Cells from a baby hamster kidney line (BHK-21) are grown as monolayers in G-MEM supplemented with 5% (v/v) fetal calf serum (FCS), 10% (v/v) tryptose phosphate broth, and 2 mM glutamine in a humidified 5% CO_2, 37°C incubator. The cells are seeded at 4 $\times 10^4$ cells/cm^2 in 10-cm tissue culture dishes (~3.2 $\times 10^6$ cells per dish) to form an even, confluent monolayer by 14 to 16 hr after seeding. These conditions yield ~1.3 $\times 10^7$ cells and ~2.5 to 3.0 mg total protein per dish at the time of the experiment. This protocol has the additional advantage that cells from 14- to 16-hr cultures can easily be homogenized. Typically, two to three 10-cm dishes are used per experimental condition, and fifteen to twenty 10-cm dishes are used for preparing stocks.

To isolate endosomal carrier vesicles, microtubules can be depolymerized prior to labeling and homogenization to inhibit transport of the marker from early endosomes to late endosomes and lysosomes. The conditions required to depolymerize microtubules may, however, vary between cell types. In BHK-21 cells, preincubating the cells 1 to 2 hr at 37°C in the presence of 10 µM nocodazole is sufficient (Gruenberg et al., 1989). No apparent depolymerization of BHK microtubules is observed after prolonged incubation at 4°C. In contrast, the depolymerization of MDCK microtubules requires both a cold treatment and an incubation at 37°C in the presence of nocodazole (Bomsel et al., 1990).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers see SUPPLIERS APPENDIX.

7.4 M medium

MEM containing:
10 mM TES [*N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid]
10 mM MOPS [3-(*N*-morpholino)propanesulfonic acid]
15 mM HEPES (*N*-2-hydroxyethylpiperzazine-*N*′-2-ethanesulfonic acid)
2 mM NaH_2PO_4
0.42 mM $NaHCO_3$
Adjust pH to 7.4
Store sterile medium 4 to 8 weeks at 4°C

Homogenization buffer (HB)

250 mM sucrose
3 mM imidazole, pH 7.4
10 mM Tris·Cl, pH 7.4 or 10 mM HEPES (*N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid)
Store sterile buffer 4 to 8 weeks at 4°C

RSU IASI CENTRAL UNIVERSITY LIBRARY

HRPO substrate solution

0.05 M sodium phosphate buffer, pH 5.0
0.3% (v/v) Triton X-100
0.342 mM *o*-dianisidine
0.003% (v/v) H_2O_2
Store at 4°C protected from light

Prepare this solution in very clean glassware to avoid contamination. Add o-dianisidine first; after it has been solubilized, add H_2O_2. Discard if a straw yellow color develops.

Internalization medium

MEM containing:
5 mM D-glucose
10 mM HEPES (*N*-2-hydroxyethanepiperazine-*N'*-2-ethanesulfornic acid)
Adjust pH to 7.4
Store sterile medium 4 to 8 weeks at 4°C

Protease inhibitor cocktail

Stock solution
10 mM leupeptin
10 mg/ml aprotinin
1 mM pepstatin
Store several months at –20°C

Working solution: Dilute stock solution 1:1000 in homogenization buffer (see recipe).

Sucrose solutions

10% (w/w) sucrose solution in D_2O
0.303 M sucrose
3 mM imidazole, pH 7.4
Store sterile solution 4 to 8 weeks at 4°C. The refractive index of this solution should be 1.3478 at 20°C.

16% (w/w) sucrose solution in D_2O
0.497 M sucrose
3 mM imidazole, pH 7.4
Store sterile solution 4 to 8 weeks at 4°C. The refractive index of this solution should be 1.3573 at 20°C.

25% (w/w) sucrose solution in H_2O
0.806 M sucrose
3 mM imidazole, pH 7.4
Store sterile solution 4 to 8 weeks at 4°C. The refractive index of this solution should be 1.3723 at 20°C.

35% (w/w) sucrose solution in H_2O
1.177 M sucrose
3 mM imidazole, pH 7.4
Store sterile solution 4 to 8 weeks at 4°C. The refractive index of this solution should be 1.3904 at 20°C.

62% (w/w) sucrose solution in H_2O
2.351 M sucrose
3 mM imidazole, pH 7.4
1 mM EDTA
Store sterile solution 4 to 8 weeks at 4°C. The refractive index of this solution should be 1.4463 at 20°C.

BCU HART / CENTRAL UNIVERSITY LIBRARY

COMMENTARY

Background Information

Subcellular fractionation was initially developed with rat liver and, in most cases, involves separation of organelles based on physical properties such as density. However, two major problems have interfered with the widespread use of subcellular fractionation in cell and molecular biology. First, studies of membrane transport and cellular organization have revealed that several subcellular compartments share similar physical properties and hence cofractionate, at least to some extent, in conventional gradients (e.g., Golgi and endosomes). In addition, the use of tissue culture cells is now widespread because cultures of cells can be manipulated in a manner impossible to achieve in animals or separate tissues. However, tissue culture cells are more difficult to fractionate than most tissues, presumably because of differences in organization of the cytoskeleton (Howell et al., 1989a).

Subcellular fractionation consists of two major steps: (1) disruption of the cellular organization (homogenization) and (2) fractionation of the homogenate to separate the different organelles. Since the early attempts to quantitatively fractionate liver tissue (Claude, 1946), methods have been developed to reproducibly disaggregate the tissue into a suspension of subcellular components and organelles called tissue homogenate (*UNIT 4.2*; DeDuve, 1955, 1971; Fleischer and Kervina, 1974; Beaufay and Amar-Cortesec, 1976). This homogenate can then be resolved by differential centrifugation into several fractions: (1) nuclei, heavy mitochondria, and plasma membrane; (2) light mitochondria, lysosomes, and peroxisomes; (3) Golgi, endosomes, and microsomes, and (4) cytosol. From these main fractions, organelles of interest can be further separated according to their size and density by additional purification steps. However, it is essential to point out that achievement of a complete purification is a barely accessible goal. Each type of organelle is composed of populations of elements that vary in size, density, and other properties on which separation relies. The complexity of tissues and cells, together with the structural alterations induced at all stages of fractionation, increases the physical heterogeneity. Additionally, the relative abundance of the organelle of interest in the cell will affect the yield in fractionation. Clearly, it is easier to purify major subcellular components (e.g., endoplasmic reticulum and mitochondria) than, for instance, transport vesicles, which are minor cellular elements. In the latter case, a low yield is often the price to be paid to achieve purification.

Subcellular fractionation

Traditional fractionation procedures are based on differences in the size and density of organelles or organelle-derived vesicles as measured in density gradients. Although sucrose is most widely used to form gradients, there are many other alternatives (e.g., Ficoll, Percoll, metrizamide, and Nycodenz). However, many of the smooth-membrane vesicles derived from the compartments involved in membrane traffic share common densities and are difficult to isolate by these procedures, so alternative methods have been developed. Table 4.3.2 lists a number of procedures that have been used to isolate endosomal fractions; see *UNIT 4.2* (and Morré et al., 1988 for a review). Gradients are extremely useful to separate populations of endosomes and lysosomes. However, gradients are often best combined with one of the techniques described below to achieve higher levels of purification. This unit describes the use of a flotation gradient combined with a method to immunologically isolate of endosomal fractions using the vesicular stomatitis virus (VSV) G protein.

Density-shift methods rely on altering the density of a specific compartment by the introduction of a perturbant. These methods have proven extremely useful for isolation of fractions from the endocytic/lysosomal pathway because of the ease with which density perturbants can be loaded into these compartments from the extracellular space. This experimental approach was pioneered by the DeDuve group, who used the detergent Triton WR-1339 to isolate lysosomes from rat liver (Leighton et al., 1968). Ligands coupled to horseradish peroxidase (Courtoy et al., 1984; Ajioka and Kaplan, 1986; Stoorgovel et al., 1987) or gold (Beardmore et al., 1987) have also been used to isolate endosomes. Golgi-derived clathrin-coated vesicles can be separated using a newly synthesized cholinesterase activity present in the vesicles (Fishman and Fine, 1987).

Free-flow electrophoresis separates subcellular compartments on the basis of charge and was first used to purify lysosomes from rat liver (Stahn et al., 1970). This method has been particularly useful for the separation of endosomes and lysosomes, which are deflected

towards the anode in the electric field. A two-step procedure in which endosomes and lysosomes are first separated from all other organelles by free-flow electrophoresis and then from each other by Percoll-gradient centrifugation has been carried out using both CHO and BHK-21 cells (Marsh et al., 1987). This work has been extended to separate two distinct populations corresponding to early and late endosomes (Schmid et al., 1988).

Immunoisolation relies on the unique localization of an antigen exposed on the outer surface of the compartment of interest, rather than on a physical property of the organelle (for a review see Howell et al., 1989b). Isolation is carried out using a specific antibody bound to a solid support (e.g., magnetic beads, cellulose fibers, acrylamide beads, or *Staphylococcus aureus* cells). The use of immunoisolation for separating different populations of endosomes is described in detail in Basic Protocol 5 and illustrated in Figure 4.3.1. This technique has been used to isolate endosomes using the cytoplasmic domain of the G protein as antigen (Howell et al., 1989a,b).

Different solid supports are available: heterodisperse polyacrylamide beads (Bio-Rad), *Staphylococcus aureus* expressing protein A (Pansorbin, Calbiochem), monodisperse magnetic beads (Dynal; Howell et al., 1989b), Eupergit particles (Röhm GmbH), and cellulose fibers (Richardson and Luzio, 1986; Luzio et al., 1988). The efficiency of immunoisolation for one particular antigen/antibody pair may vary with different immunoadsorbents depending on the abundance and/or accessibility of the antigen on the membrane of interest. Clearly, the actual immunoisolation experiment provides the only appropriate trial for selecting an immunoadsorbent. In the method described in this unit, the G protein of VSV is present at an estimated density of 80 G molecules/μm^2 membrane surface area (Gruenberg and Howell, 1987). The cytoplasmic domain of the G protein is relatively short (consisting of the 22 carboxyl-terminal amino acids) and the antibody used was raised against a synthetic carboxyl terminal peptide (Kreis, 1986). To reconstitute fusion in the cell-free assay, magnetic beads (Dynal) with a coupled linker antibody raised in sheep against the Fc domain of mouse IgG (Howell et al., 1989b) or anti-mouse polyacrylamide beads (Bio-Rad) were used. In this system >70% of fluid phase markers internalized for 5 to 45 min could be immunoisolated, by adding ≤300 μg of PNS protein to the beads; enrichment was 10- to 15-fold (Gruenberg and Howell, 1987) based on the ratio of markers immunoisolated on specific beads to markers bound nonspecifically to control beads.

The immunoisolated fractions immobilized on solid supports retain their fusion activity (Gruenberg and Howell, 1986, 1987), with

RUTGERS CENTRAL UNIVERSITY LIBRARY

only a minimal decrease in latency of fluid phase markers (Gruenberg et al., 1989). A significant advantage is that the bound fraction can be introduced into and then retrieved from a reaction mixture at the end of the reaction while bound to the solid support (Gruenberg and Howell, 1986, 1987, 1989; Emans et al.,1989). Retrieval is simple, and separation can be repeated sequentially with the same fraction through a series of experimental conditions. Separation is easily achieved with magnetic beads because they can be sedimented within minutes using a small magnet. However, a magnet should only be used to retrieve the beads after the immunoisolation step itself to limit magnetic aggregation of the beads.

By combining a flotation gradient with immunoisolation, it has been possible to purify early endosomes, endosomal carrier vesicles, and late endosomes (see Fig. 4.3.1). In the first case, the G protein was internalized for 5 min so it distributed in early endosomes. Then cells were homogenized and the PNS was fractionated on a flotation gradient. The early endosome band (interface between 16% and 10% sucrose in D_2O) was then used as input for immunoisolation. To isolate endosomal carrier vesicles (ECVs) and late endosomes, the G protein was internalized for 45 min, either in the absence of microtubules to introduce the G protein into ECVs or in the presence of microtubules to introduce the G protein into late endosomes (see Table 4.3.1 and Fig 4.3.1). After homogenization, the PNS was fractionated on the flotation gradient. In this case, the ECV/late endosome band (interface between 10% sucrose in D_2O and homogenization buffer) was used as input for immunoisolation. Thus, depending on the internalization conditions, either ECVs or late endosomes can be immunoisolated.

Analysis of subcellular fractions

The functional specialization of subcellular organelles is reflected by their morphology, protein composition, and enzymatic activities, all of which can be used to characterize and analyze purified cell fractions.

Markers

Traditionally enzymes that are localized, ideally in one cell organelle (e.g., sugar transferases in the Golgi), are used as marker enzymes for the corresponding compartments. Purification of an organelle can then be quantified by following the activity of the marker enzyme, if known, during the fractionation procedure (see example in Table 4.3.2).

The preparation of specific antibodies against proteins that localize to specific subcellular compartments has rendered biochemical and morphological characterization easier than in the past. In particular, the recently discovered large family of small GTPases, each of which has a restricted distribution, is becoming an essential tool for monitoring the composition of subcellular fractions (Zerial and Stenmark, 1993; Huber et al., 1994).

Exogenous markers can be endocytosed and thus serve as markers for endocytic organelles. The markers can be in the fluid phase or added to the plasma membrane.

Protein profiles

The protein patterns in high-resolution two-dimensional gels have been obtained for several subcellular compartments, allowing the identification of otherwise unknown proteins. In addition, the availability of two-dimensional databases (*UNIT 10.4*; Celis et al., 1994) is dramatically improving the criteria used for analysis of the protein composition of organelles.

Morphological analysis

Organelles retain many of their structural features after isolation. Therefore, electron microscopy is an important method for analyzing fractions. However, many compartments can have the same appearance—tubular or vesicular—so electron microscopy is best combined with immunocytochemistry or immunogold labeling of frozen sections.

Balance sheet

Typically, the distribution of the desired component, for example a new protein or the mutagenized form of a known protein, is compared with the distribution of known markers. Analysis of the purified fraction and assessment of the fractionation procedures requires a complete balance sheet of the values measured for the different markers that are being used, including a general marker (e.g., a protein), specific markers, and contaminants, if any. These values must be expressed so as to indicate the yield and enrichment of specific markers, as well as contaminants. The following parameters must be calculated for the different steps of the fractionation.

The **specific activity** measures the amount of the desired component in the fraction normalized to the total amount of protein. Traditionally, the specific activity refers to the activ-

ity of a marker enzyme/amount of total protein, and is measured in units/mg protein. Clearly, the amounts of the desired component can also be quantified by other techniques, for example by immunoprecipitation with specific antibodies followed by SDS-PAGE, autoradiography, and scanning of the autoradiogram.

The **yield**, the activity of the marker enzyme in the fraction/total activity of the marker enzyme or protein in the starting material (i.e., homogenate), expressed as a percentage, is a measure of the amount of the material recovered in that fraction.

The **relative specific activity (RSA)** is the absolute specific activity of the fraction/absolute specific activity of the starting material. This value provides an adequate estimate for the degree of purification achieved in each fraction.

An example illustrating the use of these parameters after fractionation of rat liver lysosomes is presented in Table 4.3.3. Fractionation is followed using a spectrophotometric assay to quantify the enzymatic activity of a lysosomal enzyme, β-*N*-acetyl-D-glucosaminidase, as described (Aniento et al., 1993b). Livers excised from rats are homogenized, then the homogenate is centrifuged 10 min at 3000 × *g*, 4°C, to prepare a nuclear/mitochondrial pellet (NM fraction) and a postmitochondrial supernatant (PMS fraction). Fraction L corresponds to the pellet obtained after two sequential centrifugations of the PMS for 10 min at 25,000 × *g*, 4°C. The pellet is then resuspended in homogenization buffer and fractionated in a metrizamide gradient (Wattiaux et al., 1978; Aniento et al., 1993b). At the end of the centrifugation, fractions are collected and analyzed. Fractions 1 to 3 are pooled together and contain mainly lysosomes. Fractions 4 to 5 contain mainly mitochondria but also some lysosomes.

Functional characterization

The use of in vitro assays has become an essential tool to study complex cellular processes in the test tube, where they can be easily manipulated and analyzed. Most steps of membrane traffic have now been reconstituted in vitro, leading to the identification of several components regulating membrane transport (Rothman and Orci, 1992; Rothman and Warren, 1994). Using an in vitro assay to monitor endosome fusion, both early and late endosomes have been observed to exhibit a high homotypic fusion activity (Tuomikoski et al., 1989; Bomsel et al., 1990; Gorvel et al., 1991; Thomas et al., 1992; Aniento et al., 1993a; Emans et al., 1993). These observations suggest that both compartments are very dynamic in vivo, which is in agreement with video-microscopy observations in vivo (Hopkins et al., 1990). However, early endosomes do not undergo direct fusion with late endosomes in vitro (see Fig. 4.3.2). Intermediate endosomal carrier vesicles mediate transport from early to late endosomes in vivo and undergo fusion with late endosomes in vitro. These carrier vesicles do not exhibit homotypic fusion properties and do not undergo fusion with early endosomes, as expected. The interactions of carrier vesicles with late endosomes is specifically facilitated by the presence of polymerized microtubules, a process that requires the presence of the minus end–directed motor cytoplasmic dynein when using nonpolarized cell extracts (Aniento et al., 1993a). In contrast, in polarized MDCK cells, both cytoplasmic dynein and the plus

POLLARD CENTRAL UNIVERSITY LIBRARY

end–directed motor kinesin are required (Bomsel et al., 1990).

The fusion of endosomal carrier vesicles with late endosomes was also characterized by immunogold labeling of cryosections in the electron microscope. In these experiments, the endosomal carrier vesicles and late endosomes from two separate cell populations were specifically labeled with 5- and 16-nm gold particles, respectively, and the corresponding fractions were then prepared using a flotation gradient. These fractions were mixed in the fusion assay in the presence of cytosol and incubated at 37°C; finally, the mixture was processed for electron microscopy. When the assay was carried out in the absence of ATP to inhibit fusion, no mixing of 5- and 16-nm gold particles was observed, and only the 16-nm gold particles colocalized with antibodies against two lysosomal glycoproteins (4a1 and 2a5), as expected. In the presence of ATP, however, both types of gold particles were mixed within the same vesicular profiles, which also contained the 4a1 and 2a5 antigens. These experiments show that, upon fusion, the 5-nm gold particles originally present in endosomal carrier vesicles were transferred to late endosomes, which contained internalized 16-nm gold particles as well as the 4a1 and 2a5 antigens (Aniento et al., 1993a). It is therefore, proposed that early and late endosomes are separate but dynamic compartments connected by endosomal carrier vesicles. These vesicles are formed from early endosomes, then they are transported on microtubules to late endosomes, where they fuse (see Fig. 4.3.2; Aniento et al., 1993a). The process of ECV formation, in particular the inclusion of internal membranes into these so-called multivesicular structures, is still unclear. Recent data, however, show that an active vacuolar ATPase is required for ECV formation (Clague et al., 1994).

Critical Parameters

The major impediment to successful fractionation of tissue culture cells is the difficulty encountered when trying to produce an ideal homogenate, that is, the release of various subcellular components (i.e., organelles) as a free suspension of intact, individual elements. Often, it is necessary to compromise between complete homogenization and damage to cellular compartments. After homogenization, cytoplasmic aggregates that contain cytoskeletal elements as well as various organelles can often be observed. To some extent, these aggregates can form after homogenization when conditions are too extreme due to the presence, for instance, of DNA released by breakage of the nucleus. However, aggregates can also reflect some cellular organization, particularly due to the cytoskeleton, that remains after homogenization. Some organelles also remain associated with cytoskeletal elements surrounding the nucleus and become entrapped in "clumps" of cytoplasm that readily sediment. As a result, as much as 50% of the components of the homogenate may be pelleted along with the nucleus during the initial centrifugation step. Because the cytoplasmic organization of different tissue culture cell lines varies enormously, homogenization conditions must frequently be optimized for each cell line.

Homogenization of tissue culture cells

Under ideal homogenization conditions, particulate organelles such as nuclei, mitochondria, lysosomes, and peroxisomes remain intact. Golgi complexes, plasma membranes, and reticular organelles will fragment and can, at least to some extent, vesiculate. However, these fragments will retain many of the in vivo activities of the corresponding organelles (e.g., protein translocation across the endoplasmic reticulum membrane). Following homogenization, nuclei are totally and exclusively removed by centrifuging 10 min at 500 to 1000 × *g* to form a nuclear pellet (NP). The PNS contains cytosol and other organelles in free suspension. It is not possible to outline a general protocol suitable for the production of a "reasonable" homogenate for all tissue culture cells, because different conditions are required for different cell types and experimental purposes. However, four parameters influence the efficiency of homogenization of cultured cells and may provide general guidelines.

Growth and experimental conditions of the cells

To achieve comparable homogenization over extended periods of time, it is essential to use cells that are grown from the same original parent culture (frozen in most cases immediately after cloning). The growth conditions of the cells must also be standarized and optimized for homogenization to remain reproducible. Cells that have been growing in a confluent state for several days are often more difficult to homogenize, possibly because they have a more complex network of cytoplasmic filaments (Kreis and Vale, 1993). In many cases, better homogenization is achieved with

ECU IAS / CENTRAL UNIVERSITY LIBRARY

cells that are 12 to 36 hr post passage, depending upon the density at which cells are seeded. Finally, the experimental conditions to which cells are subjected (e.g., prolonged cold treatment) may also influence homogenization conditions. Cells growing in suspension (or cells normally grown in monolayer but brought into suspension, e.g., with trypsin) can require significantly harsher homogenization conditions than monolayers of cells that are mechanically scraped from the dish.

Homogenization medium

Upon homogenization, the cell components are unavoidably transferred from a physiological environment to an entirely different medium. The homogenization medium should fulfill a number of basic requirements: protect the organelles against osmotic burst and possible damage due to proteases, preserve their enzymic activities and biochemical functions, prevent any kind of agglutination, minimize leakage of constituents from organelles, and interfere as little as possible with biochemical analysis and functional assays. It is obvious that it is not always possible to fulfill all of these requirements, and the most appropiate medium will largely depend on the purpose of the experiment.

To maintain the structural integrity of particulate organelles, isotonic (250 to 320 mosM) conditions at neutral pH are preferable. These conditions are also essential to retain the content within the lumen of vesicles derived from the organelles of the secretory and endocytic pathways. Some buffers appear to be more useful for the production of a monodisperse homogenate in isotonic sucrose solutions. Among these are imidazole (Beaufay and Amar-Cortesec, 1976) and triethanolamine/acetic acid (the latter first introduced for and routinely used in free-flow electrophoresis experiments; Stahn et al., 1970). Some cells are very difficult to break in isotonic buffers. The forces required also disrupt the nuclear membrane releasing DNA, which causes the cytoplasm to clump and prevents further separation. In these cases, hypotonic conditions (e.g., 3 mM imidazole or 10 mM Tris·Cl) may become necessary to achieve reasonable homogenization, but isotonic conditions should be restored as soon as possible. It may be important to include a cocktail of proteolytic inhibitors in the homogenization medium; the choice of these is largely empirical (Gruenberg and Howell, 1986; Howell et al., 1989a; Gruenberg and Gorvel, 1992).

The use of disruptive agents to depolymerize filaments of the cytoskeletal network—microtubules, microfilaments, and intermediate filaments (Kreis and Vale, 1993)—may improve the quality of the homogenate obtained from tissue culture cells. Many interactions between the cytoskeletal network and organelles are functionally significant in vivo, but must be disrupted to allow separation of individual vesicles in the homogenate. However, depolymerization of the microtubules (e.g., with nocodazole) and actin filaments (e.g., with cytochalasin) does not result in significantly better homogenization in many cases, presumably because of the presence of intermediate filaments, which are extremely difficult to depolymerize.

The addition of salts may or may not be recommended. High salt conditions (≤1 M KCl) have been used to reduce vesicular aggregation and to prevent redistribution of luminal proteins released during homogenization of guinea pig pancreas (Scheele et al., 1978). In spleen homogenates, agglutination is avoided by the addition of 0.2 M KCl (Bowers et al., 1967). However, salts can promote aggregation in rat liver and FAO cells (Devaney and Howell, unpub. observ.). High salt has also been reported to promote the condensation of intermediate filaments, a condition which is likely to increase aggregation of organelles (Steinert et al., 1982). Finally, and most importantly, high salt concentrations cause the release of peripheral membrane proteins, which can be an advantage or a disadvantage, depending on the goal of the experiment.

Homogenization devices

When the conditions of the cells and the homogenization medium are optimized, equally efficient homogenization can be obtained by many methods: by glass/glass (Dounce) or glass/teflon (Potter-Elvehjem) homogenization vessels and pestles; by repeated pipetting with a pipet or a plastic tip of an automatic pipettor (Harms et al., 1988); or by passage through a small-gauge needle with a syringe (Gruenberg et al., 1989). According to our experience, cells grown in suspension are better homogenized in a "cell cracker," a device used to homogenize cells by passage through a precision clearance (5 to 20 μm ± 1 μm) between the wall of a metal chamber and a metal ball bearing (Balch and Rothman, 1985). The choice of homogenization device often depends on the volume of the original sample.

PROTEIN CENTRAL LIBRARY

Evaluation of the homogenate

The results of homogenization should be assessed by morphological and biochemical means. Using a phase-contrast microscope, it is possible to assess the extent of cellular disruption, the appearance of intact and clean nuclei (a simple method to evaluate a good homogenization), and the absence of cytoplasmic clumps, which often appear upon overhomogenization when the nuclei start to break and the DNA is released into the cytoplasm. The quality of the homogenate is mainly revealed by its biochemical properties. Traditionally, a marker for each of the major organelles is assayed to determine its distribution in the nuclear pellet (NP) and PNS (see Table 4.3.1). In addition, the structural integrity of the organelles may be monitored by measuring the structure-linked latency of marker proteins or enzymes. With endocytic compartments, the latency of a marker endocytosed in the fluid phase can be easily quantitated.

Anticipated Results

After subcellular fractionation, the purified cellular components are characterized according to several criteria, including the composition of the fraction with respect to known markers, general protein pattern, and morphological appearance. Early endosomes, endosomal carrier vesicles, and late endosomes from BHK cells have different characteristics as summarized in Table 4.3.1.

Early endosomes can be labeled with a fluid-phase marker (i.e., horseradish peroxidase, HRPO), which is internalized from the medium during a 5-min incubation at 37°C. In addition, early endosomes have both the small GTPase rab5 (Gorvel et al., 1991) and the calcium-lipid binding protein annexin II (Emans et al., 1993) associated with the cytoplasmic surface of their membranes. Endosomal carrier vesicles can be labeled, after microtubule depolymerization, using HRPO internalized for 5 min and then chased for 45 min at 37°C (Aniento et al., 1993a). Late endosomes are labeled with HRPO internalized and chased under the same conditions in the presence of polymerized microtubules. Late endosomes contain the cation-independent mannose-6-phosphate receptor (CI-MPR; Geuze et al., 1983; Griffiths et al., 1988) and the small GTPase rab7 (Chavrier et al., 1990), and are enriched in several lysosomal glycoproteins (lgps; Geuze et al., 1983; Griffiths et al., 1988), particularly the 4a1 and 2a5 proteins (Aniento et al., 1993a).

The three endosomal compartments have also been characterized with respect to their general protein composition by analyzing the immunoisolated fractions in high-resolution two-dimensional gels (Aniento et al., 1993a; Emans et al., 1993). Early endosomes contain 50 major proteins, many of which cannot be detected at later stages of the pathway (e.g., proteins recycling with the plasma membrane). Late endosomes also exhibit a complex composition with ~50 major proteins; these include unique proteins (proteins that are not abundant, if present at all, at earlier stages of the pathway), such as 4a1, 2a5, and other highly glycosylated acidic proteins. The distribution of the 4a1 and 2a5 proteins (120 and 45 kDa, respectively) has been confirmed by cryoelectron microscopy using monoclonal antibodies. Both exhibit the physical characteristics of lysosomal glycoproteins in other cells (Kornfeld and Mellman, 1989). In contrast, endosomal carrier vesicles do not appear to contain unique proteins; >90% of the proteins they contain are also detected in late endosomes, consistent with the view that ECVs are transient elements of the pathway and function as carrier vesicles.

At the morphological level, the three components have also different appearance in BHK cells. Early endosomes consist of tubulo-vesicular elements and cisternal regions, whereas carrier vesicles are typically spherical, with a diameter ~0.4 μm and a multivesicular appearance. Late endosomes also include tubular, cisternal, and multivesicular elements but are often larger, with a diameter of ~1 μm, and (in BHK cells) typically contain large translucent inclusions (Gruenberg et al., 1989; Aniento et al., 1993a). In addition, the fate of an electron-dense tracer (gold particles) can be followed by electron microscopy after internalization in vivo. The tracer appears first in early endosomes, then in endosomal carrier vesicles, and finally in late endosomes, which can be labeled with gold particles conjugated to 4a1 or 2a5 antibodies after immunogold labeling of frozen sections. When the microtubules are depolymerized, internalized gold particles do not reach the compartments that contain the 4a1 and 2a5 antigens (late endosomes) and remain in structures that show the typical morphology of endosomal carrier vesicles.

Time Considerations

Cells for fractionation have to be seeded 14 to 16 hr before the experiment. Fluid-phase internalization takes 60 to 90 min depending on the internalization conditions (see Table

BCU IAS CENTRAL LIBRARY

4.3.1), including washes before and after the internalization step. When microtubules have to be depolymerized, an additional 60 to 90 min are required. For endosomes that will be immunoisolated using the VSV G protein, ~3 to 4 hr are required for viral fusion before internalization and an overnight incubation to bind antibodies to the beads. Once the markers have been internalized (if required), cells have to be scraped from the dishes and homogenized. It takes ~1 hr to obtain the PNS. The flotation gradient is centrifuged for 1 hr. Fractions collected from the flotation gradient can be analyzed for protein and endocytosed marker and frozen in liquid nitrogen. It is convenient to aliquot the fractions in small volumes (i.e., 50 to 100 µl) that must be frozen quickly to limit damage to the organelles. These aliquots must also be thawed very quickly and shortly before use.

Desalting, Concentration, and Buffer Exchange by Dialysis and Ultrafiltration

Various steps in protein purification result in concentrations of low-molecular-weight materials, such as $(NH_4)_2SO_4$, that exceed levels appropriate for subsequent procedures. In cases where simple dilution cannot sufficiently reduce the concentration of these impurities, dialysis or diafiltration—dialysis by ultrafiltration at constant volume—should be considered. Ultrafiltration is also convenient for concentrating protein samples without concomitantly concentrating low-molecular-weight impurities. This is achieved by forcing water and dissolved low-molecular-weight substances through a semipermeable membrane under pressure; the high-molecular-weight protein components are retained by the membrane. Alternatively, ultrafiltration can be carried out via a rapidly recirculating flow of solution over a semipermeable membrane (tangential-flow ultrafiltration). Dialysis and ultrafiltration are also effective methods for buffer exchange—i.e., the replacement of a buffer used for a previous procedure with a different buffer appropriate for a subsequent one.

Gel filtration (*UNIT 8.3*) can also be used for desalting, but because this purification technique normally employs a column containing a differentially porous gel matrix, rather than a semipermeable membrane, it is less readily adapted to large sample volumes. However, despite the availability of membranes with a wide range of porosities, dialysis and ultrafiltration are generally less efficient than gel filtration for separation of proteins on the basis of size difference, except where the difference in size is quite large (i.e., by a factor of ≥10; see Background Information).

This unit includes a variety of dialysis and ultrafiltration techniques that can be used for desalting, concentration, or buffer exchange. Basic Protocol 1 describes standard dialysis by diffusion across cellulose tubing, a technique used for desalting or buffer exchange. Basic Protocol 2 describes ultrafiltration under pressure, which can be used either for concentrating protein or, where the sample volume is replenished with a desired buffer, for desalting/buffer exchange (i.e., diafiltration). Alternate Protocol 1 describes ultrafiltration by tangential flow, which serves the same purposes as ultrafiltration under pressure but is better suited to handling large volumes of solution. Alternate Protocol 2 is an ultrafiltration technique employing centrifugal microconcentrators, which allow concentration of very small volumes of solution.

Additional information on standard dialysis using membrane diffusion is provided in *APPENDIX 3B*.

DESALTING AND BUFFER EXCHANGE BY DIALYSIS THROUGH REGENERATED CELLULOSE TUBING

BASIC PROTOCOL 1

When sample volume is <200 ml, dialysis can be accomplished by placing the sample in standard dialysis tubing immersed in a buffer of the desired ionic strength and continuously stirring the buffer. For larger volumes, multiple dialysis bags may be used, but desalting or buffer exchange on a large scale is more rapidly achieved by tangential-flow diafiltration (see Alternate Protocol 1). Because the exposure time of the sample to the buffer is relatively long, the composition, pH, and ionic strength of the buffer should be dictated by considerations of protein stability; when large volumes are involved, buffer price may be a factor as well.

BOURNEMOUTH UNIVERSITY LIBRARY

Materials

Dialysis tubing: regenerated cellulose, MWCO 12,000 (e.g., Spectra/Por Type 4, Spectrum) for general protein use or MWCO 3500 (e.g., Spectra/Por Type 3) for small proteins, stored at 4°C in plastic bag
50% (v/v) ethanol in large wash bottle
10 mM EDTA, pH 8.0
0.05 M $NaHCO_3$
Protein solution (clarified by centrifugation if necessary)
Appropriate dialysis buffer

1-liter beaker
Tubing closures, two (one weighted and one not weighted) per dialysis bag (e.g., Spectra/Por closures and weighted closures, Spectrum)
Small plastic funnel
Conductivity meter and probe (optional)

Prepare the dialysis tubing

1. Select tubing of appropriate MWCO that has a width such that the sample can be contained in sections ≤25 cm in length (see Table 4.4.1). Cut the dry tubing to the proper length, allowing an additional 10 cm for closing off the ends.

   Handle tubing only with powder-free gloves to avoid getting skin oils on membrane.

2. Immerse the sections of tubing in distilled water and rub each between two fingers until the layers separate. Using a large wash bottle containing 50% ethanol, rinse the inside and outside of each section thoroughly.

   The ethanol rinse serves to remove glycerol (used as a humectant) and residual sulfides (from the manufacturing process).

3. Mix 400 ml of 10 mM EDTA (pH 8.0) and 400 ml of 0.05 $NaHCO_3$ in a 1-liter beaker. Transfer the wetted and washed tubing to this beaker and stir 30 min using a magnetic stirrer.

4. Decant the EDTA/$NaHCO_3$ solution and replace with 800 ml distilled water. Stir 10 min on the magnetic stirrer, decant the water, and repeat the water wash. Transfer the tubing to fresh distilled water.

   If not to be used promptly, the tubing should be stored covered at 4°C in water containing 0.1% sodium azide. Once wetted, the membranes must not be allowed to dry out.

   Boiling tubing is not recommended prior to use in protein work. For more vigorous removal of glycerol and sulfide in situations where these impurities could be troublesome, the tubing may be immersed in 1 liter of 50% ethanol and heated 1 hr at 50°C,

Table 4.4.1 Approximate Capacities for Dialysis Tubing of Various Diameters

Flat width (mm)	Inflated diameter (mm)	Volume/length (ml/cm)
10	6.4	0.3
18	11.5	1.0
25	16	2.0
45	29	6.4
54	34	9.3
75	48	18

BAU IASI / CENTRAL UNIVERSITY LIBRARY

instead of being rinsed as in step 2. Regenerated cellulose tubing may be autoclaved, but this alters the MWCO. Individually packaged 14-cm lengths of radiation-sterilized tubing containing no glycerol, sulfides, or heavy metals are available at several MWCO values between 8,000 and 25,000 (Spectra/Por Biotech Sterile Membranes, Spectrum). These are suitable for small (2- to 20-ml) samples.

Dialyze the sample

5. Close one end of a washed section of tubing firmly with a weighted tubing closure. Squeeze the tubing between two fingers to remove excess water from inside.

   Alternatively, the tubing section may be closed by tying two simple overhand knots near one end.

6. Slip the open end of the tubing section over the narrow end of a small plastic funnel, then add the protein sample through the funnel. When sample addition is complete, remove the funnel and work the sample down the tubing by squeezing with the fingers to eliminate air space. Clamp the end shut with a non-weighted tubing closure (or knot the tubing carefully twice; see annotation to step 5) and trim off excess tubing. Check for leakage at both ends by applying moderate pressure to the sample area.

   Excessive air space will lead to dilution of the sample by buffer that enters and displaces air during dialysis; however, extra space should be allowed if the sample is very high in salt concentration, as it may be necessary to permit an increase in volume to prevent rupture of the bag. If the sample is very viscous, it should be diluted with the buffer against which it will be dialyzed, to facilitate outward diffusion.

7. Place the filled dialysis bag in a beaker containing a volume at least ten times the sample volume of dialysis buffer at the desired temperature, making sure that the bag is completely immersed. Stir the dialysis buffer continuously with a magnetic stirrer.

   Continual stirring serves to maximize the difference in salt concentration between the interior and immediate exterior of the dialysis bag. A larger initial buffer-to-sample ratio (≥100:1) will speed attainment of the desired final ionic strength with fewer changes of dialysis buffer. Although diffusion rate is somewhat reduced in the cold, almost all protein dialysis is conducted at 4°C to enhance protein stability.

8. Follow the progress of the dialysis by measuring the conductivity of the dialysis buffer (if this is practical). Replace the used dialysis buffer with an equal volume of fresh buffer when the increase in conductivity slows down (indicating approach to equilibrium and a drop in the efficiency of the dialysis). Continue replacing the dialysis buffer in this way until the conductivity of the buffer remains essentially unchanged after stirring for 1 to 2 hr.

   If a conductivity meter is not available, the buffer should be changed at least twice, allowing 4 to 6 hr between changes to permit the system to approach equilibrium.

   Conductivity measurements are particularly useful when large amounts of salt are to be removed and when the buffer-to-sample ratio is <100:1. In such cases, several replacements of dialysis buffer will be necessary to achieve the desired final ionic strength; conductivity measurements permit dialysis to be completed in minimum time by eliminating guesswork regarding when the system is approaching equilibrium. When a conductivity meter is not used and large samples (or tubing diameters >20 mm) are involved, it may be necessary to extend the time between buffer changes to 8 to 12 hr to insure that equilibrium is attained.

9. Remove the dialysis bag from the buffer and rinse the exterior with distilled water. While holding the bag just below the upper closure (or knot), remove that closure (or cut off the knot). Carefully tip the bag and pour the dialyzed sample into an appropriate container. Confirm that the desired salt concentration was achieved by

BOULDER CENTRAL UNIVERSITY LIBRARY

comparing conductivity measurements of the dialyzed sample and unused dialysis buffer.

If the bag is extremely taut as a result of buffer infiltration, do not cut the upper knot; instead put one end of the tubing into a beaker large enough to hold the entire sample, then puncture the tubing near the lower knot with a long needle and allow the sample to drain directly into the beaker.

BASIC PROTOCOL 2

CONCENTRATION OR DIALYSIS BY ULTRAFILTRATION THROUGH ASYMMETRIC MEMBRANE DISKS

Protein samples at an initial concentration ≤20 mg/ml can easily be reduced in volume using an ultrafiltration system and membrane, as in the protocol described below. The stirred-cell system used in this protocol—in which nitrogen gas pressure forces molecules smaller than the MWCO through the pores—is available with a variety of chamber sizes and membrane properties. Because most salts pass through the membrane along with water, the sample volume is reduced without a significant change in its surrounding buffer composition, an obvious advantage over lyophilization.

Ultrafiltration can also be used to remove or exchange salts without changing the protein concentration. This process, called diafiltration, resembles dialysis but is driven by the rate of ultrafiltration (see Critical Parameters and Troubleshooting), not by a concentration gradient. Diafiltration is carried out as in the concentration protocol here, except that continuous or periodic additions of buffer of the desired final pH, concentration, and composition are made to compensate for changes in protein concentration that would otherwise occur as a result of volume reduction.

Materials

Protein solution (clarified by centrifugation if necessary)
N_2 gas cylinder and two-stage pressure regulator capable of controlling delivery up to 100 psi
5% ethanol

Ultrafiltration membrane (YM10, Amicon; PLGC, Millipore; or Molecular/Por Type C, Spectrum) with MWCO >10,000 and diameter to fit stirred cell
Ultrafiltration unit, stirred-cell type (Series 8000, Amicon, or Molecular/Por, Spectrum) with:
- Tubing for connection to N_2 source
- Glass funnel with stem diameter to fit through cell fill hole (optional; used in certain cell models)
- Ultrafiltrate collection container (Griffin beaker with graduations)
- Pressurized reservoir (optional; for use when sample size is large and protein is dilute, or when diafiltration is performed with constant readdition of new buffer): e.g., Spectra/Chrom Pressure Reservoir (Spectrum) or RG5 Fiberglass Reservoir (Amicon)

1. Rinse a new ultrafiltration membrane with distilled water to wet it thoroughly.

Handle membrane only with powder-free gloves and hold by the edge to avoid scratching the smooth, thin "skin" surface.

Some ultrafiltration membranes can be used more than once. The Millipore PLGC (MWCO 10,000) or PLTK (MWCO 30,000) cellulose membranes are intended mainly for single use. Many other suppliers indicate that their membranes can be reused until clogged or damaged. Such membranes may be more economical, but only if each user makes sure that the previously used membrane is undamaged and properly cleaned. Amicon YM series or Spectrum Molecular/Por Type C membranes can be cleaned by soaking in 0.01 M SDS solution or 1% Terg-A-Zyme (e.g., Baxter or VWR) for several

PUU IASI / CENTRAL UNIVERSITY LIBRARY

hours; the membranes are then thoroughly rinsed with distilled water before reuse. Used, cleaned membranes should be stored covered with 5% ethanol in a closed container at 4°C. For membranes other than the ones mentioned, the manufacturer's instructions must be consulted for a suitable cleaning procedure.

2. Load the membrane into the stirred cell with the "skin" or glossy side up. Complete assembly of the ultrafiltration system, taking special care to ensure that O ring seals (if used) are not nicked and are properly placed on the membrane disk to prevent leakage around the membrane when pressure is applied.

   The size and thus the membrane diameter of the ultrafiltration cell should be as large as practical for the amount of sample to be concentrated; a larger cell reduces the necessity to refill the unit and provides the largest filtration area, speeding the concentration process. Cells are commonly available in sizes ranging from 10 to 400 ml.

3. Fill stirred cell with sample to the maximum operating volume, either by pouring the sample directly through the fill hole or by using the glass funnel provided with the cell in systems where the fill hole is small. Replace the fill-hole cover and check that the pressure-release valve (often an integral part of the fill-hole cover) is in the closed position.

   If a funnel is used, contact between the funnel tip and membrane surface should be avoided.

4. Place the unit on a magnetic stirrer and stir at the maximum rate that does not generate foam or a sizeable vortex at the surface of the solution. Direct the outlet tubing to the ultrafiltrate collection container.

   Because of protein stability requirements, most ultrafiltrations are conducted in the cold. It is advisable to check the surface temperature of the magnetic stirrer periodically; if it is warm, a styrofoam sheet 0.5-in. thick should be placed between the stirrer surface and the cell bottom.

5. Connect the cell to the nitrogen gas regulator and pressurize to 50 psi.

   Flow of liquid into the outlet tubing should quickly become evident. The system should be examined for appearance of liquid at the base of the cell where the cylinder body contacts the O ring; this indicates a leak around the membrane, in which case the unit should be depressurized and its assembly examined.

   Lower or higher pressures may be needed depending on the membrane type and MWCO value, but pressure should not exceed 70 psi in most stirred cells.

6. Monitor the flow rate and ultrafiltrate volume until the desired rate of concentration has been achieved.

   If the total sample volume exceeds the cell capacity, the cell should be refilled when the volume has decreased by one-third. Sample additions are then continued until all of the sample has been added to the cell. A pressurized sample reservoir is recommended when the sample volume is many times the cell capacity.

   At a constant temperature and pressure, the flow rate is a function of the filter area and the degree to which concentration polarization can be avoided (see Critical Parameters). Vigorous stirring is needed to minimize concentration polarization of protein at the membrane surface. Buildup of protein on the surface will result in slow filtration, even when the protein concentration of the sample is relatively low. Filtration rates at 4°C are often only one-half those seen at 25°C because of the influence of viscosity.

   Do not concentrate the sample to the point where it is no longer in contact with the stir bar, as lack of stirring will lead to severe concentration polarization in all but the most dilute samples. Overconcentration makes sample recovery difficult and may require readdition of buffer to wash the membrane, thereby adding to the volume.

BCM INSTITUTE CENTRAL UNIVERSITY LIBRARY

7. Turn off the stirrer and the nitrogen flow to the cell. Slowly release the internal cell pressure, then turn the stirrer back on and allow stirring to continue for 2 min to resuspend protein in the gel layer. Finally, turn the stirrer off and remove the concentrated sample by pouring or pipetting through the fill hole.

   If a pipet is used and the membrane is of the reusable type, care should be taken not to touch the pipet to the membrane surface. An alternative means of removing the sample is to unclamp the cell and pour out the sample, after checking that the body of the unit is firmly screwed into the base.

8. If the membrane is of the reusable type, hold it by the edges and rinse it well with distilled water. Proceed as soon as possible with the manufacturer's suggested cleaning procedure, keeping the membrane wet at all times, then store the cleaned filter in 5% ethanol in a closed container at 4°C.

ALTERNATE PROTOCOL 1

DIAFILTRATION OR CONCENTRATION BY TANGENTIAL-FLOW ULTRAFILTRATION

The most rapid method for dialyzing large samples is the use of ultrafiltration membranes fabricated into hollow fibers or spiral-wound layers, or, as in this protocol, in the form of stacked plates. The sample is allowed to flow tangentially over these membranes with recirculation. The semipermeable nature of the membrane then permits water and materials with molecular weights that are substantially below the MWCO value to cross through the membrane surface relatively unimpeded; retained materials, including the proteins of interest, are returned to the sample reservoir. To use this technique for diafiltration (as opposed to concentration), fresh dialysis buffer of the desired composition should be added to the sample reservoir in a volume equal to that of the ultrafiltrate collected, so that the concentration of macromolecular species remains unchanged. Removal of microsolutes to which the membrane is completely permeable can be estimated from the volume of ultrafiltrate (or diafiltrate, in this case) collected. Collection of an amount of diafiltrate equal to 3 vol of original sample will remove 95% of the starting solute to which the membrane is permeable, while a diafiltrate of 5 vol will correspond to a 99% separation.

The same process is used to concentrate samples, except that the retentate volume is allowed to decrease until the desired degree of concentration is reached. Maintaining a rapid flow over the membrane with a moderate transmembrane pressure minimizes concentration polarization and keeps the filtration rate high even as protein concentration in the sample increases.

The procedure described here is based on the Millipore Minitan acrylic ultrafiltration system, which employs stacked filter plates and a peristaltic pump. It is designed for sample sizes from 200 ml to 2 liters, but will work with larger samples if they are dilute. Equivalent units include the Spectrum MP-3 system and Amicon CH2PRS concentrator, both of which employ spiral-wound membrane cartridges.

DDU IASRI CENTRAL UNIVERSITY LIBRARY

Prepare the system

1. Select a filter plate of appropriate MWCO.

   Filtration rates are higher with MWCO 30,000 membranes, but the large volumes to be filtered in diafiltration may lead to some loss of proteins with molecular weight <50,000 using such membranes. Membranes of lower MWCO are also available (MWCO 1000, 3000, and 5000) but these filter more slowly and can reject some of the buffer ions, thus requiring more filtrate volume to provide complete buffer exchange.

2. Disassemble the Minitan cell to expose the lower acrylic manifold. Place the first silicone retentate separator on the acrylic surface. Carefully slip a filter plate down on the alignment pins until it is seated against the silicone separator. Follow this with the second silicone retentate separator, then another filter plate, until the desired number of filter plates have been stacked—varying the left-to-right orientation of plates at each level to permit tangential flow across each plate. After the last plate and separator have been inserted, replace the upper acrylic manifold, then the top steel plate. Complete the assembly by adding the washers and nuts, tightening them against the plate with a torque wrench to the recommended pressure.

   Layers of filter plates alternating with silicone separators can be added up to a total of 10, each with an area of 60 cm^2. Use multiple filter plates if available, especially when initial volumes exceed 2 liters. Additional filter plates increase the filtration rate in a linear fashion by providing more cross-sectional area.

3. Attach tubing to the retentate inlet on the lower manifold and run it through the pump to the sample reservoir. Likewise, attach tubing to the retentate outlet on the upper manifold and bring it to the sample reservoir. Attach a hose clamp on this section of tubing to permit the transmembrane pressure to be increased if necessary. Attach tubing from both filtrate outlets to a collection vessel; provide each section of outlet tubing with a hose clamp.

   A Y-shaped tube connector can be used to direct the output of both filtrate exit ports to a single piece of tubing.

4. Place a small amount of dialysis buffer in the sample reservoir and slowly bring the pump to a mid-range operating speed. Run the pump until the dialysis buffer has circulated through and purged the filter plates and all tubing lines. Stop the pump and discard the contents of the sample reservoir and collection vessel.

Perform ultrafiltration

5. Fill the sample reservoir with the protein sample to be diafiltered or concentrated. Restart the pump and adjust the flow to 100% recirculation by clamping off the filtrate outlets. Measure the flow and readjust the pump speed until the maximum cross-flow that provides an inlet pressure of 25 psi is achieved.

6. Open the filtrate outlets and begin collection of the ultrafiltrate.

   If filtrate flow is inadequate, some increase can be achieved by partially restricting the retentate outlet line by adjusting the screw on the hose clamp, thereby increasing the transmembrane pressure. The inlet pressure should not be allowed to exceed the recommended level for the tubing being used (usually 25 psi for silicone tubing with 4 mm i.d.). However, reduced tangential flow can lead to greater concentration polarization and ultimately a reduced dialysis rate.

   A recirculation flow/filtrate flow ratio of 20:1 may be satisfactory for dilute samples, but higher ratios are more successful at preventing concentration polarization. Because shear forces are normally not high during recirculation, protein stability is seldom reduced as a consequence of increasing this ratio.

BOKU VIBT / CENTRAL LIBRARY

7. As filtration proceeds, frequently refill the sample reservoir with fresh dialysis buffer to restore the original volume. Continue doing this until the volume of ultrafiltrate is three to five times the volume of the original sample, indicating that removal of diffusible material is 95% to 99% complete. If concentration is desired, allow the sample volume to decrease after this point until the desired volume is achieved.

8. Clamp off the filtrate line and slow the pump to terminate filtration. Remove the retentate inlet line from the sample reservoir and place it in a solution of fresh dialysis buffer, then allow the pump to push sample into the reservoir until a volume of buffer equal to the internal volume of the system has been collected (usually ~25 ml). Finally, stop the pump and remove the contents of the sample reservoir.

Clean the system

9. Clean the unit and membrane before disassembly by first pumping water through all lines to flush out remaining sample and buffer salts, then circulating 1% Terg-A-Zyme, 40°C, through the system for 30 min. Collect output from filtrate and retentate line in the same reservoir so that all solution is reused. Flush the system with 5 to 10 liters of water, discarding all output from the filtrate and retentate lines and making sure that all lines are flushed.

10. Disassemble the unit and store the filter plate(s) in 0.05% sodium azide in a covered plastic container at 4°C.

ALTERNATE PROTOCOL 2

MICROSCALE CONCENTRATION AND DESALTING WITH CENTRIFUGAL ULTRAFILTERS

Sample preparation for analytical purposes and small-scale purification may require concentration and/or desalting of volumes <1 ml. Stirred-cell assemblies (see Basic Protocol 2), although able to deal with amounts only slightly greater than that, often have unacceptably large internal volumes making sample recovery difficult. Moreover, as concentration proceeds the risk of excessive volume reduction (even to dryness) increases, because filtration with stirred cells is not self-limiting.

The advent of commercially available, single-use ultrafiltration microconcentrators powered by centrifugal force has eliminated many of these problems. These are available with a range of MWCO values in sizes suitable for handling volumes of 50 µl to 2 ml (e.g., Microcon units from Amicon). The microconcentrators can often be combined with an additional microporous membrane of 0.22-µm pore size to remove large particulates—e.g., polyacrylamide—at the same time the protein sample is being concentrated or desalted (e.g., Micropure Separator inserts from Amicon, used with the Microcon units). Centrifugal ultrafilters are also produced in sizes that will accommodate samples of ≥10 to 25 ml, but their limited membrane area and minimal remixing can result in low rates of concentration as compared with stirred cells, except when samples are dilute. Some recent designs appear to have greatly reduced concentration polarization (e.g., Centriprep from Amicon); these mostly involve improved methods of producing movement of liquid through the membrane via centrifugal force.

Additional Materials (also see Basic Protocol 1)

Centrifuge microconcentrator units: e.g., Microcon-10, -30, or -50 (MWCO 10,000, 30,000, and 50,000 respectively; Amicon); Ultrafree-MC with MWCO 5,000, 10,000, or 30,000 (Millipore); or Centri/Por with MWCO 10,000, 25,000, or 50,000 (Spectrum)

1. Pipet ≤500 µl of protein solution into microconcentrator and seal with the cap supplied by the manufacturer. When using a single concentrator or when multiple ones are not

DAU IASRI CENTRAL UNIVERSITY LIBRARY

matched in weight, prepare a balance tube (if necessary) by pipetting a volume of water equal to that of the sample into a previously used microconcentrator.

2. Place the microconcentrator opposite its balance tube in a microcentrifuge in a 4°C refrigerator or cold room. Microcentrifuge 20 to 40 min at the speed specified for the filter unit by the manufacturer.

A nonrefrigerated microcentrifuge may develop temperatures detrimental to protein samples when operated for extended periods; therefore it is usually best to have the microcentrifuge in a refrigerator or cold room for this operation, even though the filtration rate is reduced by the cold.

Microcon units can withstand forces of 13,000 × g, whereas the Ultrafree units are limited to 5,000 × g. If the sample is not sufficiently concentrated after 20 to 40 min, centrifugation should be continued an additional 20 min to see if further volume reduction occurs. Most centrifugal microconcentrators are designed to stop at a volume of 5 to 15 µl. Typical centrifugation times to concentrate 500 µl of 0.1% bovine serum albumin to 10 µl at 4°C are 25 min for the Microcon-30 and 70 min for the Microcon-10. These times are twice those observed at 25°C; recovery is ~95% in either instance.

If desalting without concentration is required, remove the microconcentrator from the microcentrifuge at the end of the centrifugation period, unscrew the sample reservoir from the filtrate tube, then pour off the filtrate from the filtrate tube. Replace the reservoir on the filtrate tube and add a sufficient amount of suitable buffer to restore the original sample volume. Replace the cap and invert to mix. If the sample does not show the desired final ionic strength as determined by conductivity measurement, repeat the centrifugation and readdition of buffer.

3. Once the desired degree of concentration has been achieved, remove the cap from the unit and place the filter portion upside down into the retentate tube supplied by the manufacturer. Place the reversed unit back in the microcentrifuge and spin 15 sec to drive the concentrate down to the tip of the tube. Remove the unit from microcentrifuge and recover the sample from the retentate tube.

With some microconcentrators, adsorption of protein to the walls of the unit as well as to the filter itself can be significant when the sample is very dilute (≤25 µg/ml). Passivation of the surfaces by soaking the entire unit overnight in 5% Tween-20, followed by thorough washing with distilled water, may help alleviate this problem. Suelter and Deluca (1983) suggest that modification of the protein solvent by addition of glycerol or Triton X-100 (below the critical micelle concentration) is superior to treatment of the surfaces of the microconcentrator.

COMMENTARY

Background Information

Used primarily for removal of excess salts or organic solvents (e.g., acetone or ethanol) employed as precipitants in protein purification or analysis, molecular separations by means of differentially permeable membranes have been an integral part of protein biochemistry since the earliest purifications. Membranes of natural origin have long been supplanted for use in dialysis by regenerated cellulose tubing. Relatively recent developments in membrane technology have provided the asymmetric designs now found in ultrafiltration membranes. This asymmetry refers to the "sidedness" built into ultrafiltration membranes, wherein a dense layer or skin ~0.1 to 0.5 µm in thickness with a carefully controlled pore size is bonded to one side of a thicker structural layer (composed of the same or different material) that has a large open-celled structure highly permeable to most molecules. A variety of materials have been used to fabricate these semipermeable membranes, ranging from cellulose and cellulose esters to polyethersulfone or polyvinylidene difluoride (PVDF). Because of proprietary interests, specific details concerning construction of these filters—particularly in regard to the more complex materials used in tangential-flow ultrafiltration—are not widely disseminated by their manufacturers. However, several

B. U. C. CHILE

PONTIFICIA UNIVERSIDAD CATOLICA DE CHILE LIBRARY

companies (Millipore, Amicon, and Spectrum) make available extensive information on their product lines and offer considerable technical advice and literature pertaining to their use.

All membranes, whether used for dialysis or ultrafiltration, are characterized by their molecular-weight cutoff (MWCO) value. This is usually defined as the molecular weight of a solute that is 90% prevented from penetrating the membrane under a chosen set of conditions. For some membranes the MWCO value is based on calibration using a mixture of dextrans, while for others it is based on calibration with specific globular proteins. How readily a particular protein is rejected by the membrane is a function of the shape, hydration state, and charge of the protein molecule. Hence, it is possible for two proteins of similar molecular weight to have decidedly different retention properties when a membrane with a stated MWCO that is near their molecular weight is used to separate them. Moreover, MWCO values are not sharp; rather, there is a gradual increase in retention as the size of solute molecules approaches and exceeds the average membrane pore size. Only at the point where all pores are smaller than a particular solute molecule is that molecule completely excluded (Saltonstall, 1992a).

In standard dialysis procedures, the requirement is for a large amount of a diffusible material to migrate through the membrane while high-molecular-weight components are retained. The rate of diffusion is influenced primarily by four factors: the concentration gradient of the diffusible material, the diffusion constant of that material, the area of the membrane, and the temperature. An increase in any or all of these variables produces more rapid dialysis; however the two that can most readily be varied are the gradient and the membrane area. The gradient should be kept large by rapid stirring of the dialysis buffer, which keeps the concentration of diffusible solutes as low as possible at the membrane exterior surface, as well as by frequent changes of the buffer solution. It is also desirable to stir the contents of the dialysis bag—which speeds up internal diffusion and minimizes concentration polarization—but this is not easily done without special equipment. The primary reason that dialysis is commonly used is that it is technically uncomplicated; even though the technique is moderately slow, arrangements intended to increase efficiency (e.g., rocking dialyzers) are rarely used (McPhie, 1971).

The rate of movement for permeable solutes in dialysis is difficult to predict, but the end state that can be achieved can be readily estimated. Ignoring possible inequality between the concentrations of low-molecular-weight ions on the two sides of a membrane that may result from a Donnan effect, the equilibrium salt concentration is predictable from simple dilution considerations. This is illustrated by the following example. If a 20-ml protein sample in 2 M ammonium sulfate/50 mM potassium phosphate is dialyzed against 1000 ml of a dialysis buffer containing 50 mM potassium phosphate without ammonium sulfate, the dilution factor will be $^{1,020}/_{20}$; thus, at equilibrium the $(NH_4)_2SO_4$ concentration will be 0.039 M. If, after equilibration, this buffer is replaced with 1000 ml of fresh 50 mM ammonium sulfate, upon equilibration the ammonium sulfate concentration will be <0.001 M. If only 200 ml of 50 mM potassium phosphate is used for each of the two buffer changes, however, the ammonium sulfate concentration in the sample will approach 0.016 M. It is thus highly desirable to change the dialysis buffer several times or to use a large ratio of dialysis buffer to sample. Both of these strategies serve to maximize the concentration differential that drives the process of dialysis towards the solute concentration present in the original dialysis buffer.

Separation by means of dialysis or ultrafiltration of two protein species that differ in their molecular weights (and R values; see Critical Parameters) is possible under some conditions, but generally will be incomplete unless the size difference is large. Saltonstall (1992b) has concluded that an efficient separation from an initial 1:1 ratio to a final 10:1 ratio would require a ratio of retention values of 10:1 (e.g., 0.9 versus 0.09), corresponding to a molecular-weight ratio of 23:1 for several different types of membrane.

Critical Parameters and Troubleshooting

Membrane impurities

Dialysis membranes made from regenerated cellulose generally contain appreciable amounts of heavy metals, with iron, zinc, and lead present at levels in excess of 1 to 10 ppm. They also contain ~0.1% sulfur from the manufacturing process. Pretreatment may be necessary to remove these materials when their presence is detrimental. Cellulose ester mem-

branes do not contain these contaminants and thus can be used directly; however they are less tolerant of organic solvents and high pH than regenerated cellulose membranes.

Ultrafiltration

The advantage of desalting processes based on ultrafiltration over those based on simple dialysis is that the rate of low-molecular-weight solute removal is not determined by a concentration differential, but rather by the flow rate of solvent and the rejection of the solute by the ultrafiltration membrane employed. The rejection (R) of a solute is defined by the relationship $R = 1 - (C_F/C_I)$, where C_F is the final concentration of the solute (in the filtrate) and C_I is the initial concentration of the solute (in the solution prior to filtration). In desalting by diafiltration, where the filtrate is replaced by fresh dialysis buffer at the same rate at which it is removed, a membrane is usually selected whose MWCO is much larger than the molecular weight of the solute to be removed. This produces an R equal to zero for the permeable solute, and, optimally, an R essentially equal to 1 (i.e., total rejection) for the protein(s) of interest—a situation in which loss of protein is minimized. When the diafiltration involves removal of a solute with an R equal to zero, the degree of washout of the solute can be calculated from the volume of filtrate collected relative to the original sample volume according to the equation: $\ln (C_I/C_R) = (V_F/V_I)$, where C_R is the final concentration of the solute in the retentate, V_F is the volume of ultrafiltrate collected (also equal to the volume of dialysis buffer added back to the sample), and V_I is the initial sample volume (which remains constant in diafiltration because of readdition of buffer). Using this equation, the volume of filtrate that must be collected relative to sample size (V_F/V_I) can be estimated for any degree of desalting required. Hence, to reduce the concentration of solute in the sample 10-fold (i.e., $C_I/C_R = 10$), the volume of filtrate collected must be 2.3 × the original sample volume; for a 100-fold reduction, this volume ratio must be 4.6.

Membranes for ultrafiltration are generally selected on the basis of the MWCO needed to retain the protein of interest but allow the maximum amount of other materials to pass through. It is usually best to choose an MWCO value that is roughly one-half the molecular weight of the species to be retained. This provides a reasonable margin of retention whereby almost none of the protein of interest should be lost, but at the same time provides the largest difference between the MWCO value and the molecular weight of the salts to be removed, thereby maximizing filtration rate. Table 4.4.2 lists flow rates for several types of membrane disks.

Concentration polarization

The term concentration polarization describes the concentration gradient of solutes (mainly those to which the membrane is not readily permeable) that forms immediately above the membrane on the side under pressure. This condition exists to some degree even at low solute levels. Concentration polarization can be reduced by efficient remixing of the solution—either by stirring action (in stirred-cell systems) or tangential movement of solution over the membrane (in tangential-flow systems). However, if the concentration of material within the gel layer at the membrane surface reaches a value that is sufficiently high, the filtration rate becomes pressure-independent and may fall to near zero.

One of the chief advantages of tangential-flow ultrafiltration systems is that they allow better control of concentration polarization than stirred-cell systems. In tangential-flow systems, concentration polarization is controlled by varying the recirculation rate of the retentate and adjusting the transmembrane pressure. Flux of filtrate through the membrane is a linear function of transmembrane pressure, until gel formation on the surface becomes the limiting factor. When this happens, increasing the velocity across the membrane surface without further increasing the transmembrane pressure will improve flux.

Adsorption of protein to the membrane

In regard to the degree of nonspecific adsorption of protein to membranes, some important differences exist among the various materials used in membrane fabrication. Most suppliers indicate that their cellulose membranes exhibit the least nonspecific adsorption of protein; these are therefore recommended for protein work even though they may have slower filtration rates than membranes fabricated from other materials. The actual amount of protein bound depends on the quantity present, its charge characteristics, and the membrane area. Even with the best membranes, losses of 1% to 5% are not uncommon when dealing with total quantities of protein in the range of 1 to 10 mg using a filter with a 43-mm diameter. The nature of the buffer can also affect adsorption of protein; some membranes

exhibit altered flow properties when high levels of ions are present. In this regard, phosphate buffers seem to present more of a problem than Tris buffers.

Precipitation of protein

Desalting sometimes results in precipitation of a portion of the protein in the sample. Although the insoluble material can be removed by centrifugation, it should not be discarded until assays establish that the desired protein has remained in solution. If the precipitated material includes the protein of interest, it can often be redissolved in a solution of higher ionic strength.

Anticipated Results

When carried out correctly, dialysis and diafiltration should produce a nearly complete recovery of the protein of interest in a buffer solution of the desired type and ionic strength. In the case of dialysis, this requires that the procedure be carried out for a sufficient time period to equilibrate the salt concentrations inside and outside the dialysis bag. In the case of diafiltration with an asymmetric membrane, this requires that a volume of filtrate be collected that is equal to approximately five times the initial sample volume.

The degree of concentration to be achieved by ultrafiltration should be that required for subsequent work. However, it should be kept in mind that once a protein concentration >30 mg/ml has been reached, further concentration is attained with increasing difficulty and production of very concentrated solutions can therefore be slow. Recovery of sample following concentration is generally >95%; failure to achieve this value usually indicates leakage into the filtrate or nonspecific binding to the membrane and/or concentration apparatus itself.

Time Considerations

Dialysis through regenerated cellulose tubing for desalting or buffer exchange usually requires 6 to 12 hr for volumes ≤10 ml and 12 to 24 hr for volumes from 10 to 200 ml. Dialysis time can be reduced by more frequent buffer changes, by increasing the ratio of dialysis buffer to sample, by increasing the surface area of the bag, and by monitoring the conductivity of the dialysis buffer to determine when the desired ionic strength has been reached.

The rate of ultrafiltration, whether performed for concentration or diafiltration, varies considerably as a function of the MWCO and surface area of the membrane and the initial

PU IAS / CENTRAL UNIVERSITY LIBRARY

sample concentration. A 10-fold reduction in sample volume (or 10-fold reduction in the concentration of a low-molecular-weight impurity by diafiltration) can usually be accomplished in 1 to 4 hr.

Selective Precipitation of Proteins

Selective precipitation of proteins (Rothstein, 1994) can be used as a bulk method to recover the majority of proteins from a crude lysate, as a selective method to fractionate a subset of proteins from a protein solution, or as a very specific method to recover a single protein of interest from a purification step. Except for antibody-mediated precipitation (see *UNIT 10.8*), selective precipitation methods are usually not protein-specific; the process depends on the physical and/or chemical interaction of the precipitating agent with one or more proteins that possess certain characteristics. It may be necessary to use a combination of selective precipitation techniques to isolate the desired protein. The success of precipitation is monitored by measuring total protein content (*UNIT 3.4*), by identifying proteins in the fractions using SDS-PAGE (*UNIT 10.1*), and by performing a suitable bioassay to identify the fraction containing the desired protein.

Developing a selective precipitation technique for a particular protein requires identification of the appropriate precipitating agent and optimization of the precipitation procedure using that agent. Often, more than one reagent will successfully precipitate a particular protein, so selecting a reagent is a matter of identifying the one that provides the desired protein in the most optimal state. Some reagents cause denaturation or adversely affect bioactivity, and some form complexes that bind the protein tightly. Still others lack the ability to selectively enrich for the desired protein. This unit describes a number of methods suitable for selective precipitation (see Table 4.5.1). In each of the protocols that are outlined, the physical or chemical basis of the precipitation process, the parameters that can be varied for optimization, and the basic steps for developing an optimized precipitation are described.

Clarification of Samples

If raw samples are laden with particulate matter that cannot be centrifuged (at 5 to 50 × *g*) or filtered out by ordinary means, sometimes suspensions can be clarified by filtration on a 2- to 4-mm layer of "filter-aid" material—e.g., Filter-Aid (Schleicher and Schuell)—on Whatman no. 1 filter paper. Several kinds of filter aid materials for particulate and gelatinous samples are available—e.g., cellulosic fibers (Filter-Aid from Schleicher and Schuell or Hyflo Supercel from Fisher), diatomaceous minerals (e.g., Celatom from Aldrich, kieselguhr from Baxter, or diatomaceous earths from Sigma), silicates (e.g., Celite from Aldrich), specialized clay absorbents, calcium minerals, bentonite, or Fuller's earth. These should be experimented with—e.g., by adding 0.05 to 0.2 g of the material to 1 to 2 ml of the sample to find out which filter aid adsorbs gelatinous or particulate material without excessive adsorption of the protein. The layer or pad of filter aid for use with the main sample is prepared by adding a few grams to the filter paper and distributing it evenly by puddling it with water while pulling moderate suction on a Buchner funnel.

Frequently, a means for freeing proteins in solution from particles and haze by centrifugation or simple filtration can be quickly worked out by adjusting the pH or salt content (or both). The pH may be adjusted up or down by one to three pH units; also, salt may be added to make particulates and colloidal material easier to centrifuge or filter out. Bioactivity assays should be carried out even at the clarification stage to ensure that pH changes and salt additions did not destroy the activity or functions of the proteins to be isolated. Figure 4.5.1 summarizes the steps in clarification of protien solutions.

If the conservative techniques for clarification (filter aids and pH/salt variation) do not work, more aggressive techniques may be used that employ some of the rather powerful particle and colloid agglomerating agents such as synthetic polyelectrolytes (described below; see Basic Protocol 6), or metal-ion flocculating agents such as aluminum ions. These need to be added in quite limited amounts (in micrograms to a few milligrams per ml of sample), cautiously and slowly, to coagulate unwanted particles without precipitating sought-for proteins at this preliminary clarification stage. An advantage of metal ions as particulate coagulants or filter aids is that any excess of metal ions can be conveniently removed by conventional cation-exchange resins in K^+, Na^+, or NH_4^+ form (see Basic Protocol 2).

Unwanted particulates like whole cells, cell membranes, and haze may also be removed by centrifugation in some samples. However, for very large volumes (and where centrifugation is not successful) filtration using filter-aid compounds is frequently useful.

Pressure membrane ultrafiltration (*UNIT 4.4*) with a large MWCO (>30,000) may be tried if such membranes pass the sought-for proteins and hold back the haze particles.

Concentration of Samples

Very dilute samples beyond the reach of normal precipitating agents for proteins may need to be concentrated before adding precipitating agents. Lyophilization (freeze-drying) is sometimes successful for concentrating certain proteins that are able to withstand removal of virtually all water. However, a majority of proteins, including clotting-cascade and many blood plasma and cytosol proteins, cannot withstand lyophilization. It is more generally preferred, therefore, to use pressure membrane ultrafitration (*UNIT 4.4*) with a membrane of appropriate MWCO to concentrate sought-for proteins while keeping them cautiously in solution.

crude sample, particulate/haze laden
haze-removal steps: clarify by precipitation:
pH shift, 2 to 4 pH units up or down
salt (NaCl) addition plus pH shift
precipitating agents, limited amount, to precipitate particulates but not proteins in solution
clarify by centrifugation (500–1000 × g) or filtration over filter aid on Whatman no. 1 paper; use pressure membrane (high MWCO) filtration if necessary
particle-free protein in solution:
assay protein content and bioactivity; adjust total protein concentration (by pressure membrane ultrafiltration using low to medium MWCO to remove water if necessary) to bring it into range of 0.1% to 2% total protein (depending on precipitative technique to be used); see Table 4.5.1
perform pilot experiments for optimizing one of the precipitative techniques in Table 4.5.1

Figure 4.5.1 First steps and options for clearing particulates—e.g., haze and cell walls—from crudes before precipitating proteins. Limited amounts of precipitating agents may be effective in removal of haze from proteins. However precipitating agents for haze removal should not reach lower threshold concentrations for starting precipitation of sought-for proteins. Abbreviation: MWCO, molecular-weight cutoff.

Often it is best not to overconcentrate—i.e., not to attempt to remove nearly all of the water but to get the sought-for proteins to >1% to 2% weight concentration—before precipitating. Unwanted materials such as cell debris, polysaccharides, glycoproteins, and lipoproteins, may precipitate out early, coprecipitate desired proteins, or otherwise become difficult to deal with when they are overconcentrated. In some instances it may be the best choice to dilute samples with a buffer that can also shift pH, then carry out the concentration step. A general starting range of desired protein concentration (clear of haze) is 0.01% to 2%.

Pilot Experiments

After the protein sample has been clarified and concentrated (if needed), aliquots of haze-free sample should be placed in small test tubes or 2-ml plastic centrifuge tubes. A series (Fig. 4.5.3) or a 3 × 3 or a 4 × 4 grid of tubes (Fig. 4.5.11) are used. At first, buffers should be added to the aliquots of sample in rather large steps, at intervals of 1 or even 2 pH units. As the procedure is developed, much narrower pH intervals will be used to zero in on the optimum pH, depending on where bioactivity and protein-specific activity assays locate sought-for proteins in each tube. Likewise, in the first pilot experiments one may make rather large, well-spaced strides in concentrations of precipitating agents added—perhaps 5- to 10-fold differences between pilot samples to locate the neighborhood of precipitation versus nonprecipitation for chosen agents. Then, in a second series, more narrowly spaced conditions should be used to get smoother control over precipitation.

DUKE / CENTRAL UNIVERSITY LIBRARY

Protein precipitation and coprecipitation frequently are quite cooperative (in the equilibrium sense of the term) like other types of phase changes—i.e., protein precipitations may tend to be all-or-none processes. Therefore good control sometimes can be obtained only within small ranges of conditions, such as in variation of precipitating agents. However, the neighborhood or range of parameters where that can be achieved may best be located by the first, wide-ranging set of experiments.

Pilot experiments should make it possible to decide whether the process shall be one of first precipitating out desired proteins, as opposed to first taking out unwanted proteins and perhaps other materials and then bringing down desired proteins in a second stage.

Investigation of optimum temperatures is usually useful and even mandatory. Pilot samples may be kept in refrigerators, at room temperature, and at still higher (heat-shock) temperatures, to find the best temperatures for both protecting and precipitating proteins. Protein precipitation, even when optimized, is sometimes nearly as dependent on rates (kinetics) as on equilibria (thermodynamics). In practice, therefore, attention must be paid to controlling the time of incubation of pilot samples under the various conditions. Strong precipitating agents (synthetic polyelectrolytes are leading examples) may form coprecipitates within a few seconds, but be irreversible. Intermediate and even quite weaker precipitants may take hours to develop protein coprecipitates but afford more controllability and reversibility.

Choice of Procedure

Table 4.5.1 lists ten possible techniques for protein precipitation. Choice of which to use likely depends on how easy or difficult it may be to reverse precipitation to recover the protein(s) and discard excess precipitating agent. For most uses to which precipitated proteins are put—e.g., nutrition, therapy, or simply for assay—the proteins must be freed of precipitating agents. The quite powerful agents, such as synthetic polyelectrolytes, can be difficult or slow (or both) to remove and release from desired proteins. Consequently, synthetic polyelectrolyte coprecipitation may best be used for first bringing down unwanted proteins (i.e., where those precipitates are to be discarded). Remaining proteins in the supernatant may then be captured using a less aggressive but more controllable, reversible precipitating agent from the list in Table 4.5.1 (e.g., Basic Protocols 1 to 5 or 8 to 10).

Removal of Nucleic Acids

Crude proteins from cell cytosols, especially from bacteria and yeasts, may be laden with nucleic acids (RNA and DNA). Nucleic acids may interfere with protein isolation and contribute to haze and colloidal character. It is useful to remove nucleic acids in the early stages of crude workup. Techniques for removal of nucleic acids also help remove some kinds of particulates when the particulates have much anionic character—e.g., many cellular and subcellular membranes. There are two general methods for removing nucleic acids—i.e., precipitation using polyamines (*UNIT 1.3*) and using positively charged anion-exchanger resins (*UNIT 6.1*). Nucleic acids are polyanions that are charged negatively and rather densely with phosphate groups. Naturally occurring "protamines" (Felix, 1960; Budavari, 1989), which are proteins themselves, but very cationic proteins, thoroughly coprecipitate most nucleic acids and ribosomes. However, overshooting the endpoint—i.e., adding more than enough protamine proteins to remove the nucleic acids—may leave excess protamines in samples, contaminating the sought-for proteins and perhaps interfering with their isolation downstream. Accordingly, it may be necessary to determine the endpoint for stopping protamine addition using a suitable spectroscopic technique for nucleic acid content (see *UNIT 7.2*). Synthetic polyethyleneimine (PEI; Sigma) and syn-

BCU IAS CENTRAL UNIVERSITY LIBRARY

thetic polyamino butane compounds (spermine; Sigma) also precipitate nucleic acids, and are useful for large samples (milliliter to liter in volume). A detailed review of PEI (also called Polymin by some vendors) for nucleic acid precipitation is found in Jendrisak (1987). Between 20 and 80 µl of 5% PEI, added per ml of crudes containing 4% (dry weight) nucleic acids, nearly completely removes nucleic acids. This procedure should be carried out at a pH of ~7.5 to 8, where PEI amine groups are fully cationic and nucleic acids are fully anionic. However, PEI is a very able precipitant for proteins with isoionic points below pH 7. If the sought-for protein coprecipitates with both PEI and nucleic acids, as some enzymes do, pH variation and salt extraction (e.g., with NaCl; Jendrisak, 1987) then becomes necessary to free such enzymes from the PEI agglomerate.

Anion exchangers may also be used to remove nucleic acids and have an advantage and a disadvantage compared to polyamines used in solution. The advantage is that an excess of solid exchanger may adsorb less of the sought-for proteins than an excess of such reagents as PEI in solution. The disadvantage is that—because solid resins can only adsorb very large macromolecules like nucleic acids at the resin surface (not in its interior)—rather large quantities of resin may be required. The Amberlite IRA-400 series of resins (Sigma) and Dowex-1 anion exchangers (Sigma) are adsorbants for nucleic acids in neutral pH ranges. The DEAE-celluloses (Sigma), which are quaternized amines and therefore cationic, also are capable of adsorbing nucleic acids to remove them from crudes preliminary to isolating the proteins from the crudes. See Basic Protocol 2 for directions on washing and conditioning such resins prior to use.

SELECTIVE PRECIPITATION BY SALTING OUT

BASIC PROTOCOL 1

Ammonium sulfate is the best, first-choice salt for initial development of a salting-out program to precipitate sought-for proteins (see Fig. 4.5.2). Other salts may be chosen, and frequently they yield successful results. However because of sulfate's kosmotropic and protein-molecule exclusionary powers (see Commentary), ammonium sulfate is most preferred and best understood. Sulfate salting out may be both thermodynamically limited and rate-limited. If precipitation of proteins does not occur quickly after addition of estimated amounts of sulfate salt, it may be best to wait for a period, perhaps a few hours, to allow time for precipitates to form. This becomes necessary for dilute protein solutions—less than ~1% in overall concentration. For several mammalian enzymes, the threshold for protein precipitation and solubility—i.e., the visibly seen development of precipitation versus proteins remaining dissolved (apparent equilibrium)—occurs at ~2 to 5 mg/ml protein in 2 to 3 M ammonium sulfate, at neutral pH (Scopes, 1987).

The pH and temperature also are likely to be important. If the isoelectric pH of the sought-for protein is known, it may be used as the center point around which to vary pH, in increments of ~0.5 to 1 pH unit, in initial searches for optimum conditions. A number of proteins, peptide antibiotics, and drugs are best salted out as coprecipitates with SO_4^{2-} as a bound counterion. Hence their optimal pH for salting out may be acidic with respect to their isoelectric point. Figure 4.5.2 illustrates the main steps in salting out, starting with mixtures of proteins in solution without particulate matter.

In both this protocol and Alternate Protocol 1, the sample is first carried through all steps on a small scale for a pilot experiment to determine optimal conditions. The procedure is then scaled up to purify the protein sample, using those optimal conditions. Figure 4.5.3 illustrates the procedures for such a pilot experiment.

BCU ASTON CENTRAL UNIVERSITY LIBRARY

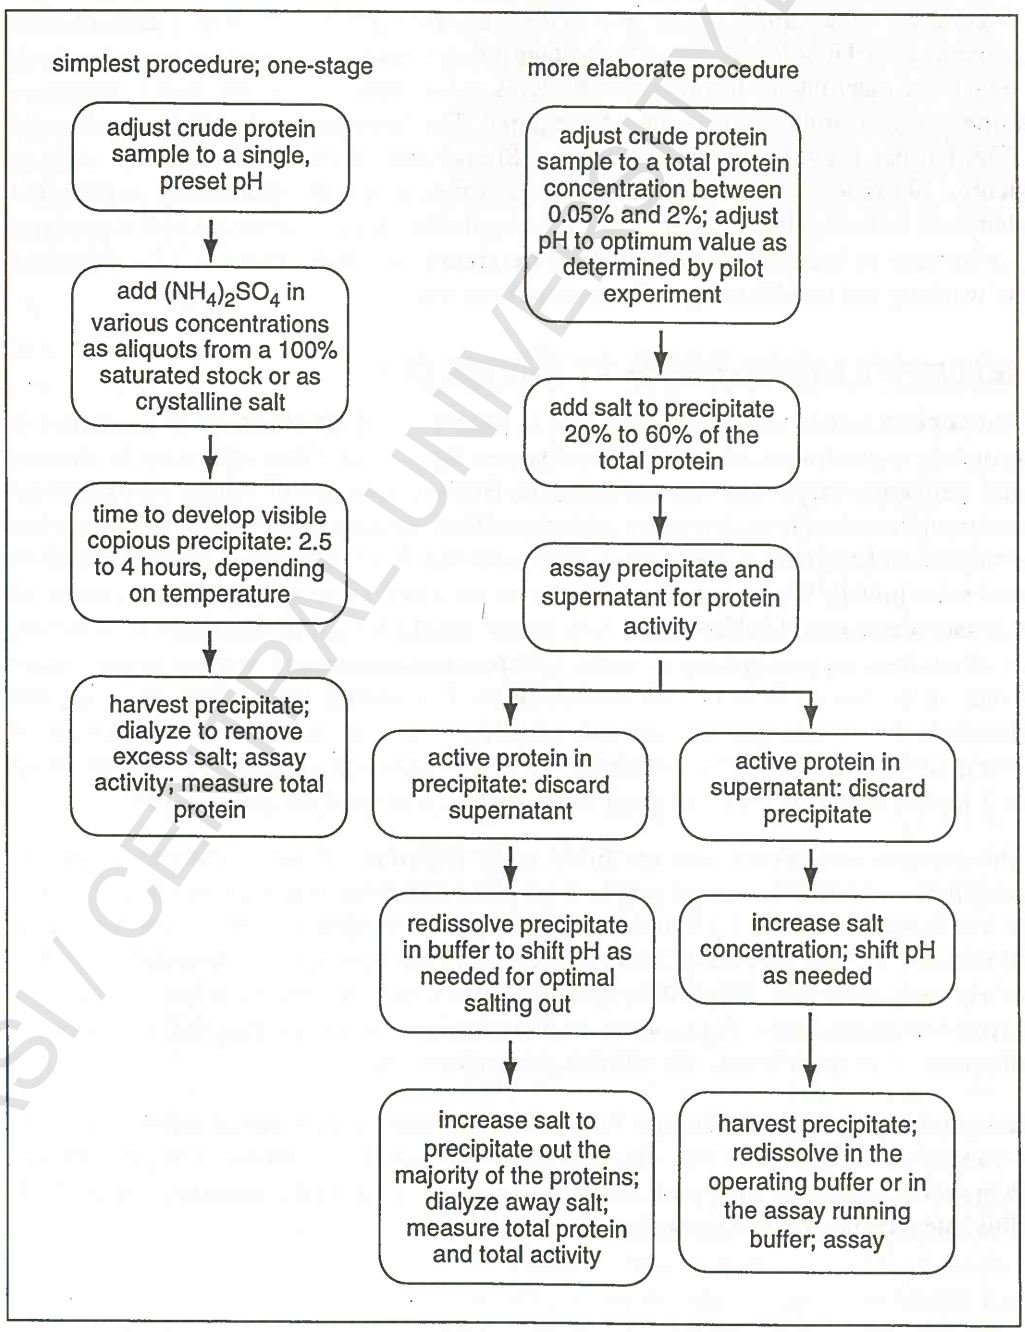
Materials

Crude protein solution of interest, particle-free (see discussion of Clarification in Strategic Planning)
Appropriate pH buffer
Ammonium sulfate

Additional reagents and equipment for dialysis (*UNIT 4.4 & APPENDIX 3B*)

1. Dialyze protein samples against a pH buffer or a pH buffer/ammonium sulfate mixture having a sulfate concentration below that needed to start precipitation (see *UNIT 4.4 & APPENDIX 3B*).

   By carrying out dialysis, three objectives may be achieved at the expense of an added step. First, it is possible to dialyze out unwanted lower-molecular-weight materials—e.g.,



simplest procedure; one-stage
adjust crude protein sample to a single, preset pH
add $(NH_4)_2SO_4$ in various concentrations as aliquots from a 100% saturated stock or as crystalline salt
time to develop visible copious precipitate: 2.5 to 4 hours, depending on temperature
harvest precipitate; dialyze to remove excess salt; assay activity; measure total protein
more elaborate procedure
adjust crude protein sample to a total protein concentration between 0.05% and 2%; adjust pH to optimum value as determined by pilot experiment
add salt to precipitate 20% to 60% of the total protein
assay precipitate and supernatant for protein activity
active protein in precipitate: discard supernatant
redissolve precipitate in buffer to shift pH as needed for optimal salting out
increase salt to precipitate out the majority of the proteins; dialyze away salt; measure total protein and total activity
active protein in supernatant: discard precipitate
increase salt concentration; shift pH as needed
harvest precipitate; redissolve in the operating buffer or in the assay running buffer; assay

Figure 4.5.2 Two-salting out protocols, single-stage and two-stage, starting from a particle-free aqueous crude preparation (e.g., cell or tissue extract or centrifuged fermentation broth).

RCU IASI / CENTRAL UNIVERSITY LIBRARY

sugars, amino acids, and components of fermentation broth or cell extract. Second, dialysis makes it possible to bring the protein sample smoothly to the prescribed pH. Finally, dialysis allows the investigator to adjust the protein sample to a known beginning salt concentration—that of the dialyzing buffer. Such dialysis may be carried out in dialysis bags (cellulose acetate tubing), or by pressure membrane concentrators with membranes having nominal molecular-weight cutoff points below that of the sought-for protein.

2. Set up a pilot experiment (see discussion of Pilot Experiments in Strategic Planning) to determine the optimal protein concentration, pH, salt concentration, temperature, and incubation time.

   See Critical Parameters and Troubleshooting for guidelines on how to vary these parameters. See Figure 4.5.3 for illustration of a small-scale pilot experiment.

   pH adjustments generally are performed by addition of acid (HCl), base (NaOH, KOH, or ammonia), or a buffer. At the same time, it is usually necessary to avoid adding too much overall volume, so the buffering capacity of the sample itself must be taken into account. If feasible, it is generally best to adjust pH of proteins with ~0.1 or 0.2 M HCl, or comparable concentrations of aqueous ammonia. Trying to move the pH appreciably with buffers, if dilute buffers must be used, increases overall volumes and decreases salt concentration. That, in turn, may require the use of considerably more salt to reach a specified concentration, in contrast to operations where pH has been adjusted by use of HCl or NaOH.

   CAUTION: *The protein solution should be stirred well during addition of strong acid or strong base. Beware of changes in temperature.*

3. Add ammonium sulfate to the optimal concentration (see Critical Parameters and Troubleshooting). Incubate (for the optimal period of time) until a precipitate forms.

   The salt may generally be added as a saturated solution. However, there is an advantage to adding the salt in solid form, as increases in volume are thereby lessened. There are few indications that addition of solid ammonium sulfate does harm to proteins already in solution.

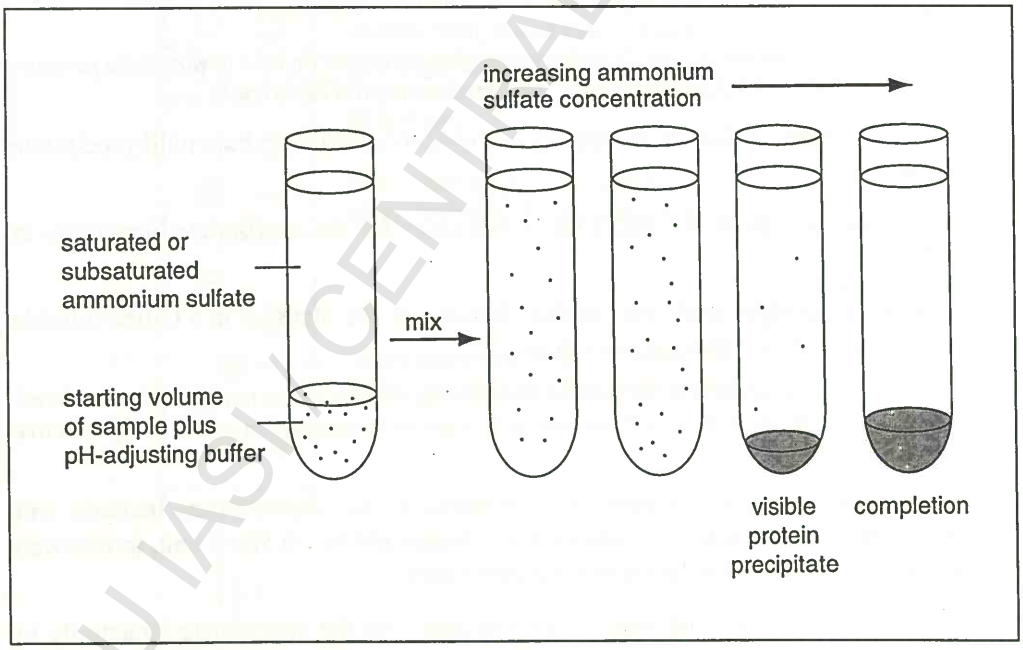


Figure 4.5.3 Salting out—small-scale investigation. Maximum ammonium sulfate concentration ~4 M. Development of precipitate depends on the protein and unwanted materials which sometimes precipitate out in samples or fractions, apart from the sought-for protein. Other adjustable parameters are pH, temperature, and concentration of starting sample.

EMU IAS CENTRAL UNIVERSITY LIBRARY

4. Collect the precipitate by simple decantation (pouring off the supernatant).

   Ammonium sulfate precipitates are usually dense and settle out readily. However, if simple settling and decantation will not work, a slow-speed centrifugation (10 to 100 × g) should easily suffice.

5. Redissolve the precipitate in a buffer suitable for the next step (e.g., running buffer for electrophoresis or assay buffer).

   High concentrations of K^+ and other salts are not compatible with SDS-PAGE and isoelectric focusing. K^+ salts of SDS are poorly soluble. Large amounts of ammonium ion grossly interfere with some total protein assays (UNIT 3.4). Therefore, excess salt should be dialyzed away by simple cellulose-tubing dialysis (UNIT 4.4 & APPENDIX 3B) or by pressure ultrafiltration (UNIT 4.4).

6. Perform a bioassay for the protein of interest.

   If the sample is to be diluted considerably for the bioassay, the redissolved ammonium sulfate may not need to be dialyzed beforehand. However, if appreciable salt interferes (as in SDS-PAGE and total protein assays), the assay may require a dialyzed sample input.

ALTERNATE PROTOCOL 1

SELECTIVE PRECIPITATION BY STEPWISE SALTING OUT

A stepwise salting-out procedure is used to fractionate a crude mixture into two portions, only one of which retains the desired protein. The result is a partial purification of the desired protein from a crude mixture of proteins; this may improve the extent of recovery in subsequent purifications.

In this protocol, as in Basic Protocol 1, the sample is first carried through all steps on a small scale for a pilot experiment to determine optimal conditions. The procedure is then scaled up to purify the protein sample, using those optimal conditions. Figure 4.5.3 illustrates the procedures for such a pilot experiment.

1. Adjust the concentration and pH of the crude protein solution to the optimal values as determined by a pilot experiment (see discussion of Pilot Experiments in Strategic Planning).

   See Critical Parameters and Troubleshooting for guidelines on how to vary these parameters. See Figure 4.5.3 for illustration of a small-scale pilot experiment.

2. Add ammonium sulfate at an appropriate concentration. Incubate until precipitate forms.

3. Collect the precipitate and supernatant and assay for the appropriate bioactivity in each.

4a. *If the active fraction is the precipitate:* Redissolve the material in a buffer suitable for assay or the next general procedure.

   If the next steps are not to be performed immediately, the precipitate need not be redissolved. It should be stored with its salt because salts, especially ammonium sulfate, are protective and stabilizing.

4b. *If the active fraction (or part of it) remains in the supernatant:* Increase salt concentrations by 5% to 10% and perhaps change pH by ~0.5 to 1 unit, in renewed pilot experiments and in larger-scale precipitation.

5. Collect the precipitate and supernatant and assay for the appropriate bioactivity in each.

6. Repeat steps 4b and 5 until the protein of interest is obtained in as clean a preparation as possible.

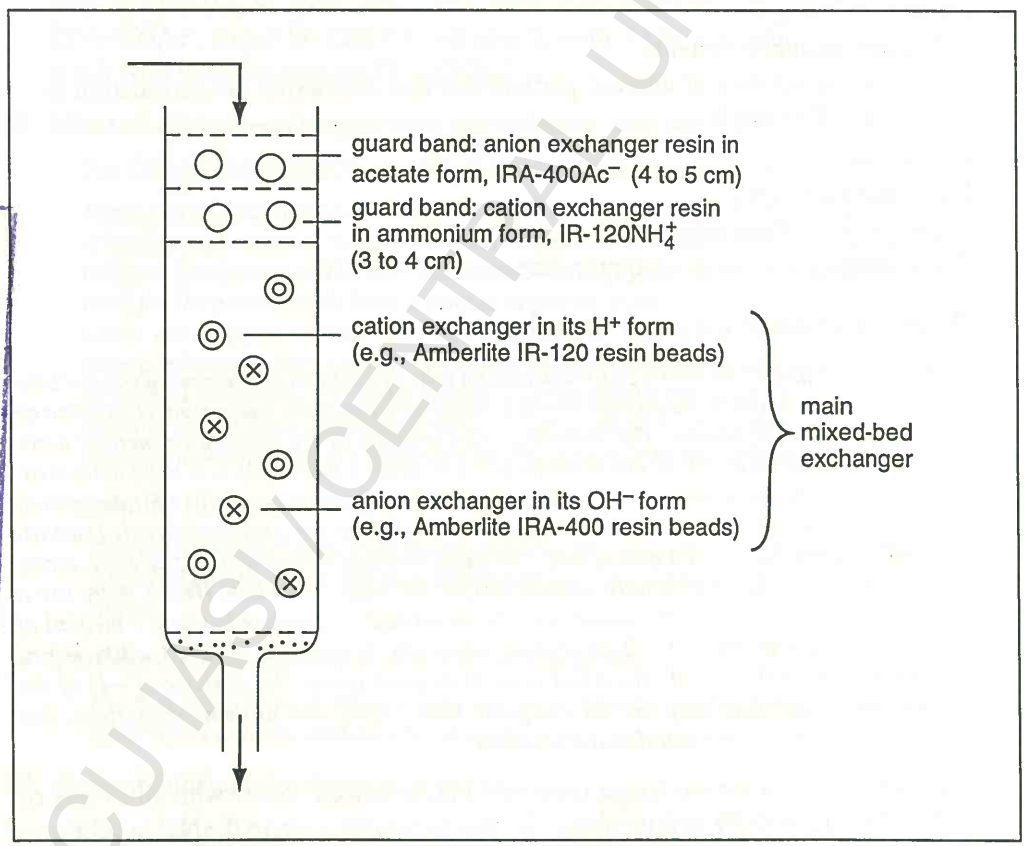
BCU IASI / CENTRAL UNIVERSITY LIBRARY

SELECTIVE PRECIPITATION BY ISOIONIC PRECIPITATION: COLUMN METHOD

Proteins frequently are least soluble and most precipitable when they are isoionic. In the isoionic, salt-free state, protein molecules are in their most compact, least hydrated conformation—a phenomenon that is closely related to the condition of proteins at their isoelectric point. The distinction between isoionic and isoelectric properties is drawn in detail by Tanford (1961). Deionization using a column (this protocol) or dialysis (see Alternate Protocol 2) aim at rendering proteins isoionic to precipitate them. Two important parameters determine solubility of many proteins: solution pH with respect to each protein's isoionic point (pI) and the low salt concentration (zero to 0.1 to 0.2 M salt). A number of proteins—e.g., β-lactoglobulin—are sharply dependent on these parameters. Accordingly, if these parameters are well controlled and carefully adjusted, the solubility/precipitability behavior of a protein will be a practical basis for scaleable, selective isolation of the desired protein. The column method used in this protocol is appropriate only for proteins that remain soluble at their isoionic point.

In addition to adjusting proteins to their isoionic pH, the general method described here, using mixed-bed resin deionization, is able to strip away all salts from proteins. Salts, even in small concentrations (<0.05 M in many cases) often have large effects on protein solubilities and therefore on precipitability. Inorganic salts tend to "salt in" many proteins, thus enhancing their solubilities. Accordingly, sharp control and thorough removal of salts as desired is an important part of the general technique of isoionic precipitation.

Figure 4.5.4 shows a Dintzis deionization column with a lower, main mixed bed of anion-cation exchange resin beads in their respective OH^- and H^+ form. Two categories



guard band: anion exchanger resin in acetate form, IRA-400Ac⁻ (4 to 5 cm)
guard band: cation exchanger resin in ammonium form, IR-120NH₄⁺ (3 to 4 cm)
cation exchanger in its H⁺ form (e.g., Amberlite IR-120 resin beads)
anion exchanger in its OH⁻ form (e.g., Amberlite IRA-400 resin beads)
main mixed-bed exchanger

Figure 4.5.4 Deionization column, Dintzis design, described in Edsall and Wyman (1958). Passage through this column renders the protein salt-free and automatically adjusted to the protein's isoionic pH. This column is used for proteins that remain soluble at their isoionic point.

B. C. U. „M. Eminescu" IAŞI CHIMIE

BCU IAŞI / CENTRAL UNIVERSITY LIBRARY

of salt ions are removed by the mixed bed: (1) the supporting electrolyte—i.e., the free salt in the solution; and (2) salt ions that are counterions, which are in effect bound to the protein if the protein is not isoionic. If the pH of the starting solution is below the isoionic point, the protein is a cation with anion counterions, commonly Cl^-. If the pH is greater than the isoionic point, the protein is a net macroanion with cationic counterions, commonly K^+ or Na^+. In the mixed bed, cationic and anionic salt ions are exchanged for H^+ and OH^-, respectively, going on to simply form water. Protein molecules deprived of all mobile counterions are quantitatively forced to the single pH at which they can exist without mobile counterions or protein-bound ions—i.e., the isoionic pH. Therefore the effluent of the column is isoionic protein at the isoionic pH, in plain water. The net salt exchange and entrapment processes are similar to conventional desalting by resin ion exchangers, except the effluent is buffered by the isoionic protein and adjusted to its pH.

In the original Dintzis column, illustrated in Figure 4.5.4, guard exchanger bands may be positioned at the top of the column above the main bed. They exchange incoming salt cations and anions (or protein counterions) for NH_4^+ ion and acetate ion from the resins. This is intended to protect incoming proteins from direct mixing with the equivalent of strong acid and strong base, respectively, from the mixed-bed strong exchange resins in their respective H^+ and OH^- form. The NH_4^+ and acetate ions are exchanged and removed in the main bed, and the isoionic protein sample flows through.

Materials

Cation exchanger: Amberlite IR-120H^+ resin (Sigma or Aldrich)
Anion exchanger: Amberlite IRA-400Cl^- resin (Sigma or Aldrich)
~0.5 and 1 M NaOH or KOH
0.5 to 1 M HCl
0.2 M acetic acid
0.2 M ammonium hydroxide
Crude protein solution of interest, particle-free (see discussion of Clarification in Strategic Planning)

Plastic beakers
Large Buchner funnel
Whatman no. 1 filter paper
Chromatography column of appropriate size

1. Determine exchange capacity required.

   Necessary capacity for deionizing and trapping salts depends on the number of counterions and therefore on pH of the protein solution, concentration of the supporting electrolyte or buffer, and overall volume. The following is an example of the calculation method used. Assume that 50 ml of 5% serum albumin in 0.2 M acetate buffer, pH 4, is to be deionized. On the basis of the titration curve (with a pI of 5.0 for albumin; see UNIT 8.2 for discussion of titration curves), ~35 counterions (e.g., Cl^-) are present per protein molecule (mol.wt. 67,000), amounting to ~1.3 meq of ions. The buffer contains ~10 meq of total acetate, along with 10 meq of Na^+, which were counterions for the buffer's acetate. Hence, there are a total of 22 meq of ions to be exchanged. The mixed bed is calculated to hold 1 meq/ml of settled mixed-bed resin, so ~12 ml of resin, minimally, is required. Thus a 2 × 30–cm bed including 80 to 90 cm^3 of mixed-bed resin is in good excess (by a factor of ~4) of the minimum required to strip out all inorganic ions, buffer, and protein counterions. See Critical Parameters for additional discussion.

2. Place IR-120H^+ cation-exchange resin in a plastic beaker, cover with an excess of ~0.5 M NaOH or KOH, and incubate ~20 min to convert resin to the Na^+ or K^+ form. Transfer to a large Buchner funnel containing Whatman no. 1 filter paper, wash with water, then transfer to a beaker and cover with an excess of 0.5 to 1 M HCl. Incubate

BCU IASI CENTRAL UNIVERSITY LIBRARY

20 min, then transfer to a Buchner funnel containing filter paper and wash with water again. Repeat this exchange cycle at least one more time before mixing the exchange resins.

This full-cycle treatment removes undesirable low-molecular-weight hydrolysis fragments from resin polymers, which otherwise would bind strongly to many proteins and elute with them when proteins are passed through the column. Each step requires ~20 min, to allow penetration, diffusion, and exchange of ions with the interiors of the resin beads. More detailed specifications are given in full treatises describing exchangers, such as Kressman (1957) and in the manufacturers' literature.

3. Place IRA-400Cl^- resin in a plastic beaker, cover with an excess of ~1 M NaOH or KOH, and incubate ~20 min to convert resin to the OH^- form. Transfer to a large Buchner funnel containing Whatman no. 1 filter paper and wash with water to remove all excess OH^- ion.

   The resin is now IRA-400OH^-. It should be kept cold and should not be exposed to air during long periods of storage because the CO_2 in air slowly neutralizes the IRA-400OH^- to a bicarbonate form. The resin should be taken through this full exchange cycle within a few days prior to use.

   Anion exchangers, both old and new, which are made of quaternary amine polymers, self-hydrolyze and slough off organic amines, especially when stored in their hydroxyl form (e.g., IRA-400OH^-). Accordingly, IRA-400 in whatever starting form (Cl^- or OH^-), needs be taken through a full exchange cycle. Each step requires ~20 min, to allow penetration, diffusion, and exchange of ions with the interiors of the resin beads. More detailed specifications are given in full treatises describing exchangers, such as Kressman (1957) and in the manufacturers' literature.

4. Prepare resin for preexchange guard bands as follows. React IRA-400OH^- (from step 3) with 0.2 M acetic acid, then wash with water to prepare anion-exchanger IRA-400Ac^-. React IR-120H^+ (from step 2) with 0.2 M ammonium hydroxide, then wash with water to prepare IR-120NH_4^+.

5. Mix and load ion-exchange resins into columns (also see Fig. 4.5.4).

   See Critical Parameters for guidelines on preparing the mixed-bed resin.

   Some precautions need be taken to prevent unmixing—i.e., formation of separated bands of cation and anion exchangers in their respective H^+ and OH^- forms—when filling the column. The density of IR-120H^+ is appreciably larger than that of IRA-400OH^-. The resins used for the guard bands have a similar disparity in density. If large volumes of premixed resins are dropped through several centimeters of water, they unmix on the way down. Hence, mixed-bed resins should be dropped in small increments, with forward flow of water, to prevent unmixing. The same general considerations pertaining to procedures such as packing and loading chromatographic columns, dead-volume minimization, and prevention of channeling that are described in UNIT 8.4 apply to this column technique.

6. Determine flow rate required.

   If there is adequate capacity in the mixed bed to trap all salts, a 2 × 30–cm column deionizes 50 to 100 ml of a 1% to 5% protein solution in ~3 hr. Suitable flow rates average 0.5 to 1 ml/min.

7. Perform column separation on crude protein solution.

   The first cut, ~20 to 30 ml of eluate, will be quite dilute as the protein solution displaces water in the column, and may be set aside.

8. Perform bioassay for the protein of interest.

9. Recycle used resins.

   Mixed-bed resins previously used for deionization—e.g., of serum proteins—are good general binding agents and can be reused. After being used for deionizing a protein, the

BOUVIER CENTRAL UNIVERSITY LIBRARY

resin should be flushed with 0.2 M HCl to remove any protein and to prevent bacterial growth. Mixed-bed resin pairs of the IRA-400 and IR-120 series, as well many of the Dowex resin pairs, separate well from one another in saturated KCl. Crystalline KCl can be added to a slurry of used mixed-bed resin in water. As KCl saturation approaches, the anion exchanger that is least dense—i.e., the Cl^- form—floats upward. The cation exchanger in K^+ form sinks. The anion-exchange resin slurry is decanted off the top, away from the cation exchanger, isolating both resins. These may then be individually recycled back to their respective OH^- and H^+ forms, whereupon they may again be mixed as needed (see steps 2 and 3).

ALTERNATE PROTOCOL 2

SELECTIVE PRECIPITATION BY ISOIONIC PRECIPITATION: DIALYSIS METHOD

One of the older means of rendering proteins salt-free or nearly salt-free (i.e., isoionic) is dialysis (also see *UNIT 4.4 & APPENDIX 3B*). However, two problems frequently arise with conventional dialysis: (1) when appreciable amounts of protein are present, osmotic effects result in swelling of dialysis bags as salt diffuses outward; and (2) often it is quite uncertain where the isoionic point is, even if it is feasible to deionize by dialysis against a buffer. The resin deionization method (see Basic Protocol 2), sometimes called Dintzis' method (Edsall and Wyman, 1958), automatically adjusts a protein precisely to its isoionic pH without prior knowledge of it.

Proteins that precipitate immediately when deionized are troublesome in the column method described in Basic Protocol 2 and Figure 4.5.4. Precipitates plug the column and pose the problem of separating precipitated protein from resin beads. β-lactoglobulin and a number of other proteins behave in this way; they have solubilities very sensitive to low salt conditions near the isoionic pH. This protocol (also see Fig. 4.5.5) describes a means of overcoming this problem. Proteins to be deionized and precipitated in isoionic form are confined in dialysis tubing with a molecular weight cutoff that will retain the protein of interest and the mixed-bed resin is placed outside as a slurry of 40 to 60 g of mixed-bed resin (50 to 80 ml of wet resin; see Basic Protocol 2) per 200 to 400 ml of dialyzing solvent. Salt ions and protein counterions exchange through the membrane and are trapped outside in the exchanger resins. After exchange is completed, precipitated protein in the dialysis tubing is recovered by centrifugation of the bag's contents. This general technique requires several hours. Salting out and diffusion slow as the protein concentration inside the dialysis bag decreases; hence this method is slower than the flow-through column method (see Basic Protocol 2).

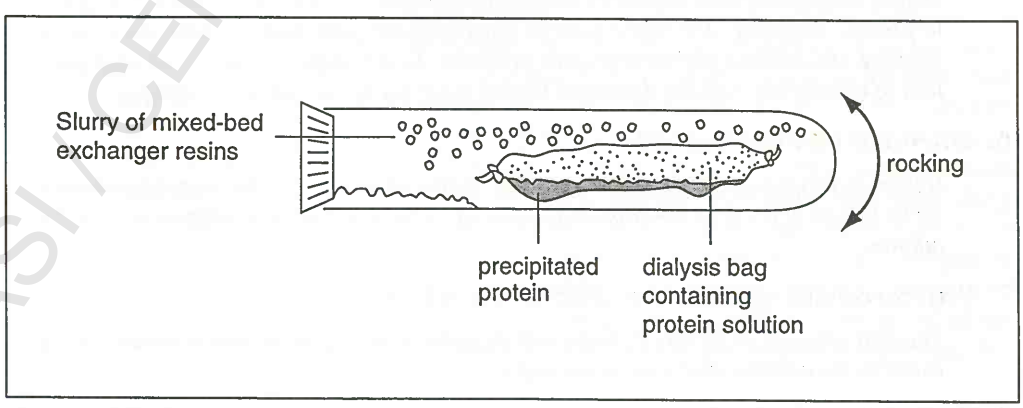


Figure 4.5.5 Deionization by dialysis. When proteins are insoluble and precipitate at their isoionic point, deionization is accomplished by placing dialysis tubing containing the protein sample in a slurry of mixed-bed resin exchangers (i.e., a mixture of IRA-400OH^- and IR-120H^+) and incubating with rocking. Proteins insoluble at their isoionic point precipitate inside the bag. The mixed-bed exchange resins remove free salts, forcing the protein to its isoionic pH. This method is considerably slower than the column method.

RCU IASI / CENTRAL UNIVERSITY LIBRARY

SELECTIVE PRECIPITATION USING A TWO-CARBON (C_2) ORGANIC COSOLVENT

Protein precipitation using very cold ethanol or acetone is a method that was developed over a century ago. Both of these cosolvents are still frequently used. Ethanol surpassed acetone for precipitating proteins at the time E. J. Cohn, and co-workers at Harvard perfected the Cohn fractionation (Cohn et al., 1946) for large-scale preparation of plasma proteins—albumin, fibrinogen, prothrombin, and γ-globulins. The Cohn procedures are still employed, although modified. One of the advantages ethanol has over acetone pertains to fire hazard. Ethanol is less volatile than acetone and generates less flammable vapor under otherwise similar conditions. Both cosolvents, when handled in in >0.1-liter amounts, should be used in ventilated rooms.

Materials

Crude protein solution of interest, particle-free (see discussion of Clarification in Strategic Planning)
Buffering system
Ethanol
Acetone
Centrifuge

1. Adjust the crude protein solution of interest to the selected pH.

   If the operating buffer (used as the solvent in the separation) or pH-calibration buffers (used to check pH-meter calibration) are to be selected for low-temperature operation, the tables by Alner et al. (1967) and Perrin and Dempsey (1974) give formulations for several buffers together with their pH values at temperatures in the 0°C range.

2. Arrange for good stirring and good metering to control mixing of organic cosolvents with the aqueous proteins.

   It is necessary to suppress local high concentrations of C_2 cosolvents. It is also necessary to suppress the heat generated by mixing of cosolvents, especially of ethanol with water, to avoid undue denaturation and temperature increases greater than ~2°C above the set temperature. Dilution of organic cosolvents with water or with aqueous running buffer before they are added to the protein solution may repress generation of heat during mixing and may also repress formation of large local concentrations of cosolvents at the point at which they are mixed with aqueous protein. However excessive dilution of organic cosolvents may add to the final volumes necessary to reach precipitation thresholds. A 3% to 8% (v/v) volume of water in organic cosolvent is a suitable dilution for achieving protein precipitation before overall volumes become excessive.

3. Cool the two components—i.e., protein in aqueous buffer and cosolvent system to be used—to the running temperature. Do not allow temperatures to rise more than 2°C above the running temperature.

   Lower temperatures can be obtained by using an auxiliary refrigeration unit pumping coolant through an exchanger coil or by incubating C_2 cosolvents in the deep freeze. Salt/ice baths are capable of reaching approximately –10°C.

4. Slowly mix the the cosolvent system into the aqueous protein solution while monitoring the mixture with a thermometer.

   If the temperature rises much during cosolvent (or cosolvent/buffer) addition, slow the rate of solvent addition down to let the cooling system remove excess heat. Predilution of organic cosolvents (see annotation to step 2) may be helpful here.

5. Collect precipitate by centrifugation or allow precipitate to settle out. Remove supernatant and redissolve precipitate by adding water or suitable aqueous buffer.

BCIT IRSI / GERRARD UNIVERSITY LIBRARY

Organic cosolvents admixed with aqueous systems usually decrease the density of the solvent mixture, which may aid settling or centrifugation of precipitated protein. However, the centrifuge should also be cooled down to the precipitation running temperature. Some centrifuges become surprisingly warm, depending on the vintage and specific features. A test of the actual centrifugation temperature is advisable; this is done simply by immersion of a thermometer in centrifuge vessels after a run.

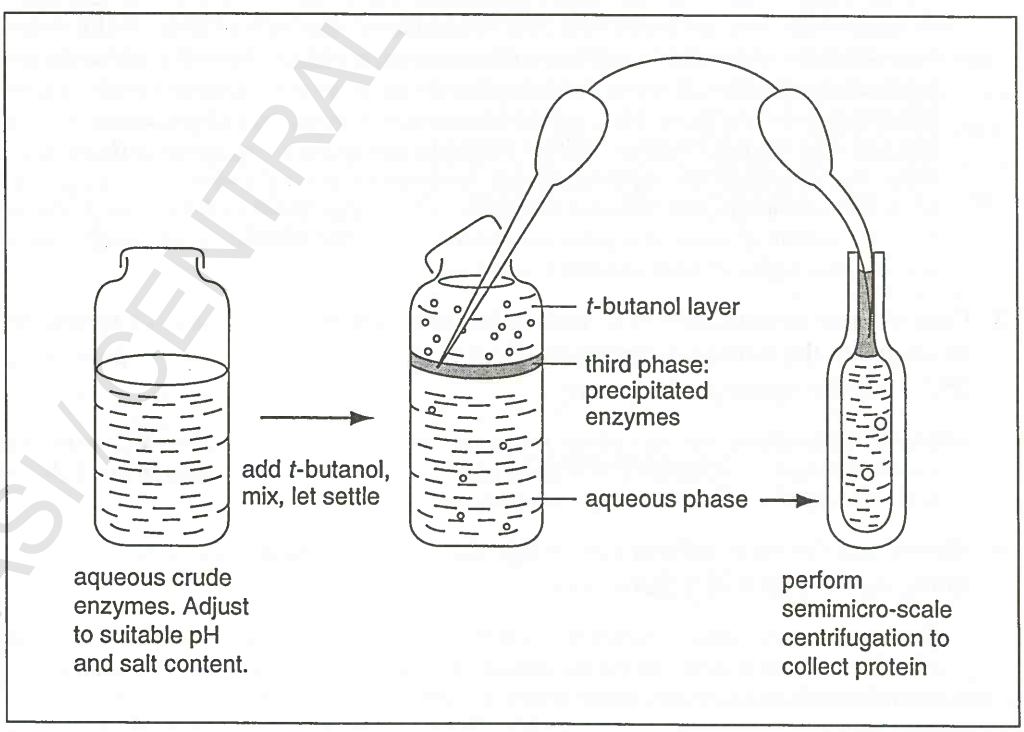
6. Perform a bioassay for the protein of interest.

BASIC PROTOCOL 4

SELECTIVE PRECIPITATION USING C_4 AND C_5 ORGANIC COSOLVENTS

Figure 4.5.6 outlines the technique for three-phase partitioning (TPP) using *t*-butanol in conjunction with ammonium sulfate (Lovrien, et al., 1987). Some C_5 and C_6 cosolvents—e.g., alcohols such as pentanol—may be useful in some cases. However C_5 and larger cosolvents tend to be so insoluble in water as to be of limited use. The cosolvent used here, *t*-butanol, is infinitely soluble in water alone, but in the presence of large concentrations of ammonium sulfate it forms a second phase. Simultaneously, proteins are precipitated, forming a third phase intermediate between the lower (aqueous) and upper (organic) liquid phases (see Fig. 4.5.6). The various phases are mutually saturated with respect to one another. The protein precipitate is usually well developed and easily retrieved by low-speed centrifugation.

TPP behavior depends on protein molecular charge (precipitated products are often sulfate salts of protein). Therefore, the pH of the aqueous phase is an important parameter for modulating protein precipitation, partitioning, and extraction of unwanted compounds. When proteins have been extracted from their original source using detergents, TPP or related methods such as Morton's *n*-butanol extraction technique (Morton, 1950) are frequently effective in removing detergents, lipids, and pigments from the sought-for protein.



t-butanol layer
third phase: precipitated enzymes
aqueous phase
add t-butanol, mix, let settle
aqueous crude enzymes. Adjust to suitable pH and salt content.
perform semimicro-scale centrifugation to collect protein

Figure 4.5.6 Procedure for precipitation of proteins from aqueous solutions using *t*-butanol. This figure applies to both large-scale precipitation and small-scale pilot experiments. The *t*-butanol layer develops when adequate salt is present in the aqueous solution. Both the *t*-butanol layer and the aqueous lower phase act as extraction solvents as well as partitioning systems.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

Materials

Ammonium sulfate
Buffering system
Crude protein solution of interest, particle-free (see discussion of Clarification in Strategic Planning)
C_4 organic cosolvent (e.g., *t*-butanol, analytical grade)

1. Add ammonium sulfate and buffer to adjust the salt concentration and pH of the crude protein solution of interest appropriately.

   The amount of ammonium sulfate used is determined by pilot experiments and is in general less than that used for simple salting out (20% to 100% saturation); i.e., the amount added is less than sufficient to induce precipitation.

2. Add ~0.5 to 1 ml C_4 organic cosolvent per ml crude protein solution, mix, and incubate until three phases form.

   If only technical grade t-butanol is available it may be either recrystallized (the melting point of pure t-butanol = 25.5°C) at room temperature, or distilled (the boiling point = 82°C).

3. Transfer the middle phase containing the precipitated protein to a centrifuge tube of volume approximately twice that of the protein precipitate. Centrifuge at $10 \times g$, 4° to 25°C.

   See Critical Parameters for discussion of the separation of phases.

4. Redissolve the precipitate in an appropriate buffer and perform suitable bioassay.

SELECTIVE PRECIPITATION USING PROTEIN EXCLUSION AND CROWDING AGENTS AND OSMOLYTES

BASIC PROTOCOL 5

Protein exclusion and crowding agents and osmolytes are neutral, very water-soluble compounds—such as sugars, organic diols, and polymers—used in concentrations of 2% to 20% to precipitate proteins. They operate primarily by entropically driven "crowding" (Herzfeld, 1996), by preferential hydration (Timasheff, 1992), or a combination of both mechanisms. Such agents push proteins out of solutions in the mechanical/physical sense and in the thermodynamic sense. At concentrations greater than ~5% by weight, exclusion agents and osmolytes occupy so much volume on the molecular scale that they leave less room in solution available for protein molecules.

Crowding and molecular-exclusion polymers that have been used for protein precipitation include polyethylene glycol (PEG), polypropylene glycol (PPG), polyvinyl alcohol (PVA), methylcellulose, dextran, and hydroxypropyldextran. Osmolytes and zwitterions used for protein precipitation include sucrose, 2-methyl-2,4-pentanediol (MPD), raffinose, maltose, sarcosine, and betaine. These compounds are readily available from suppliers such as Sigma and are able to protect and precipitate a number of proteins. Development of each protein-precipitation program requires attention to pH, temperature, and other factors that modulate parameters governing protein solubility and precipitability. The literature is scant concerning rate limitation of protein precipitation by these parameters. It is likely that in lower concentration ranges of proteins, neutral polymers, and osmolytes (<1% to 2%), precipitation rates may be slowed. Accordingly the general method should be treated as a rates (kinetics) problem when precipitates are not quickly formed.

The sample is first carried through all steps on a small scale for a pilot experiment to determine optimal conditions. The procedure is then scaled up to purify the protein sample, using those optimal conditions. Figure 4.5.3 illustrates the setup for such a pilot experiment.

BOU MACHINE UNIVERSITY LIBRARY

Materials

Crude protein solution of interest, particle-free (see discussion of Clarification in Strategic Planning)
Appropriate pH buffer
Precipitating agent: neutral polymer or osmolyte

1. Set up a pilot experiment (see discussion of Pilot Experiments in Strategic Planning) to determine the optimal concentrations of protein and precipitating agent as well as the optimal pH, temperature, and incubation time.

   In preliminary searches, use a series of test tubes as in Figure 4.5.3. On addition of components to each other, mixing or strong vortexing may be needed because some neutral polymers are highly viscous.

2. Prepare protein solution and solution of precipitating agent.

   Neutral polymers should be dissolved in water before adding them to aqueous proteins. Moderate heating may speed dissolving. It is poor practice to attempt addition of dry polymers directly to dissolved proteins as the polymers tend to form gummy masses that dissolve very slowly.

   Mechanisms here depend on molecular crowding; hence concentrations of proteins and dissolved polymers to be added must be maximized. These components dilute each other when mixed. If protein samples need pH adjustment before the mixing step, use buffers in fairly concentrated form—or even 0.2 to 1 M acid or base if feasible—to keep volumes minimized and component concentrations maximized.

4. Mix protein solution and solution of precipitating agent. Incubate (for the optimal period of time) until a precipitate forms.

   If mixtures of proteins are very crude and only one or two proteins are sought after, it may be preferable not to drive the precipitation too hard. In such cases it may be best to accept more slowly developed precipitates to maximize the amount of unwanted protein and excess precipitant left behind in the supernatant and the amount of sought-after protein captured in the precipitate.

5. Collect the precipitate.

   Trapped and coprecipitated neutral polymers in precipitates may need be "reversed" or split away later to release proteins free of polymers. How this can be done depends on the chemistry of the systems, and perhaps also on the chromatographic properties of the precipitated proteins. In the case of dextrans, modest amounts can be degraded by dextranase enzyme. Coprecipitated proteins may be captured on ion-exchange matrices, whereupon neutral polymer may be eluted and the protein displaced from the exchanger using a pH shift and/or salt (see UNIT 8.2).

6. Perform bioassay for the protein of interest.

BASIC PROTOCOL 6 SELECTIVE PRECIPITATION USING SYNTHETIC AND SEMISYNTHETIC POLYELECTROLYTES

Four categories of polyelectrolytes can precipitate proteins. First, there are the synthetic polyelectrolytes—e.g., vinyl polymers such as polyacrylate (PAA) and polymethacrylate (PMA); acid salts (polyanions); and polyethyleneimine (PEI, a polycation). Next, there are the semisynthetic polyelectrolytes—carboxymethylcellulose (CMC), sulfated cellulose, and sulfated dextrans. The third category includes the protamines (very basic proteins), and the fourth includes naturally occurring sulfate polysaccharides—e.g., heparin and chondroitin sulfate. Heparin and related biochemical polyelectrolytes are not generally used on a large scale because of their cost; they are used in research for precipitating narrow classes of proteins such as β-lipoproteins. For a recent, short review

of polyelectrolytes for protein precipitation see Singh (1995). Table 4.5.2 lists a number of polyelectrolytes in each category and cites references regarding their use. Figure 4.5.7 outlines the main steps for polyelectrolyte-mediated protein precipitation.

Frequently, the main practical problem with this technique is in reversing coprecipitation—i.e., dissolving the coprecipitate in a way that releases proteins and splits away the polyelectrolyte. In the case of polyacrylate and polymethacrylate, these polymers bind calcium and barium ions rather strongly. Thus protein/polyacrylate coprecipitates may first be shifted upward in pH, which renders proteins and polyelectrolytes negatively charged and helps them redissolve. After this, Ca^{2+} or Ba^{2+} is introduced to precipitate away the polyelectrolyte and release the protein. Several papers describing examples of the use of this technique are referred to in the Commentary (see Critical Parameters and Table 4.5.2).

The general range of starting protein concentrations from which proteins may be coprecipitated in fair to good yield (at optimum pH) is ~0.05% to 3% (w/v) protein. The range of quantities of polyelectrolyte required, given a suitable kind of polyelectrolyte, tends to be less than the amount of protein. By weight, ~2% to 20% polyelectrolyte with respect to the protein is generally required. The variation between systems is large, partly because polyelectrolytes have large variations in charge density—e.g., completely ionized polyacrylic acid carries one anionic charge per 56 g polymer; carboxymethylcellulose, substituted on each glucose unit, carries one anion per 240 g polymer if completely ionized.

Materials

Water-soluble polyelectrolytes (Aldrich or Sigma)
Crude protein solution of interest

Test tubes
Glass or plastic cuvettes
Spectrophotometer

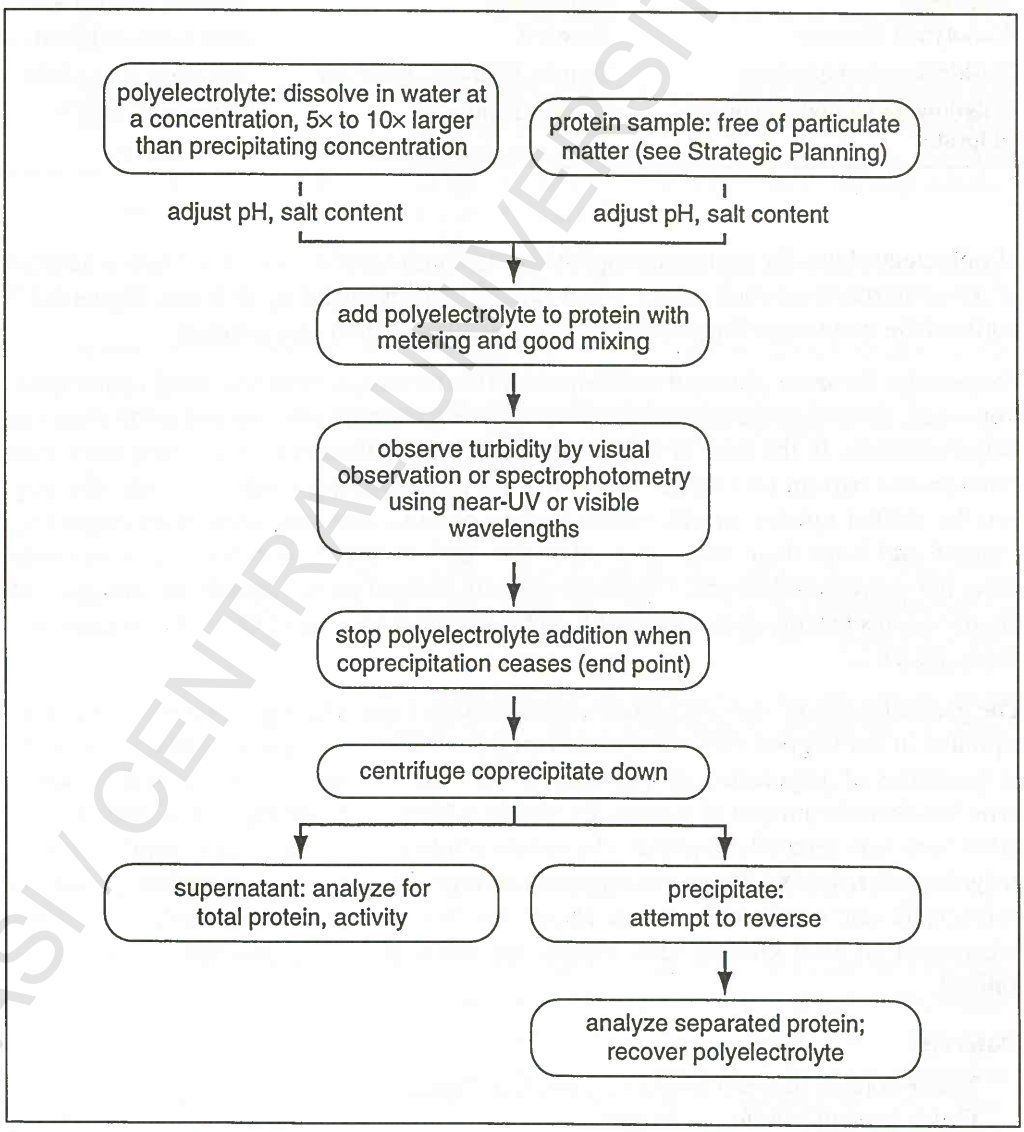
BCU IAS CENTRAL UNIVERSITY LIBRARY

1. Choose a polyelectrolyte.

For proteins not previously investigated, first experiment with from two to four easily available, water-soluble polyelectrolytes. Polyacids (e.g., polyacrylic acids), and polybases (e.g., polyethyleneimine), can be titrated with NaOH, or HCl respectively, to two or three pH units, respectively, above or below the target protein's isoelectric point (if known). Such polyelectrolytes are buffers themselves, as are proteins, over the pH range of acid/base titration. Hence, it is unnecessary to use additional conventional inorganic buffers to control pH. If polyelectrolytes and proteins are mismatched in pH before mixing, the mixture may shift in pH; the pH should be measured, if necessary, to determine H^+ transfer on mixing the main components.

2. Prepare stock polyelectrolyte solutions.

Initial stock polyelectrolyte solutions should be prepared in water in concentrations three to ten times the final coprecipitating concentrations. Dilutions will be performed in the succeeding steps.



polyelectrolyte: dissolve in water at a concentration, 5× to 10× larger than precipitating concentration
protein sample: free of particulate matter (see Strategic Planning)
adjust pH, salt content
adjust pH, salt content
add polyelectrolyte to protein with metering and good mixing
observe turbidity by visual observation or spectrophotometry using near-UV or visible wavelengths
stop polyelectrolyte addition when coprecipitation ceases (end point)
centrifuge coprecipitate down
supernatant: analyze for total protein, activity
precipitate: attempt to reverse
analyze separated protein; recover polyelectrolyte

Figure 4.5.7 Principal steps in protein coprecipitation with polyelectrolytes. "Metered" addition is slow addition (with good stirring) of aliquots of polyelectrolyte stock to the protein sample near the threshold of precipitate formation as seen by eye or spectrophotometric turbidity determination.

RCU IASI / CENTRAL UNIVERSITY LIBRARY

3. Render protein sample clear and nonparticulate (see discussion of Clarification in Strategic Planning).

4. Set up several test tubes on a small scale, adding ~2 ml sample and 0.05 to 1 ml of each polyelectrolyte stock solution at three or four different pH values to construct a matrix of polyelectrolyte/protein mixtures. Observe the point at which turbidity appears.

   The intent is to roughly locate (by visual comparison to detect turbidity) the coprecipitation starting point, the coprecipitation end point, the relative concentrations of polyelectrolyte and protein to be used, and the optimum pH. This enables construction of a rough phase diagram (i.e., a plot of turbidity versus variables such as relative amount of polyelectrolyte).

   Also see discussion of Pilot Experiments in Strategic Planning.

5. Set up a more finely grained pilot experiment as in the previous step, but carry out turbidity measurements in glass or plastic cuvettes. For scale-up, use controlled rates of polymer addition (i.e., adding polymer to the protein sample slowly in reproducible aliquots of stock solution near the threshold of precipitate formation), temperature control (water bath), and mixing using a magnetic stir-bar. Measure spectrophotometric absorbance in the 400- to 500-nm range and determine where overt coprecipitation begins.

   Sharply climbing absorbances mark the ranges where turbidity forms as a result of particulate coprecipitates. Coprecipitation is in large part a rate process as well as an equilibrium process. If the aim is to achieve selection of particular proteins, rather than precipitation of all proteins, the best strategy may to bring down some protein(s) in a first-stage separation of the coprecipitate, followed by a second stage in which polyelectrolyte is again added.

6. Carry out full-scale separation. Centrifuge to collect coprecipitate; retain the supernatant and analyze for total protein activity.

7. Reverse coprecipitation to free captured protein from synthetic polymers.

   This step should start with resuspension of particles in water or in buffers to shift pH to a position where polyelectrolyte and protein have similar charges—e.g., both anionic or both cationic. Separating out polyelectrolytes is often achieved by addition of metal ions (Ca^{2+} or Ba^{2+} in the form of chlorides) to carboxylate polyelectrolytes. An attempt may also be made to adsorb polyelectrolytes on bead resins of opposite charge—e.g, on DEAE cellulose for carboxylated polyelectrolytes.

   In developing a procedure for polyelectrolyte removal and release of sought-for proteins, measurement of supernatant protein concentration and/or activity if the protein is an enzyme should facilitate monitoring of protein release. Most of the polyelectrolytes in Table 4.5.2 have low A_{280} absorbances (and small molar extinction coefficients). Hence simple measurement of A_{280} should locate the conditions at which proteins are released into solution, provided there are no particulates present. However, such particulates cause very strong scattering and turbidity in the UV range, far beyond the absorbance of equivalent amounts of truly dissolved protein.

8. Perform bioassay for protein of interest and recover polyelectrolyte.

BCU IAS CENTRAL UNIVERSITY LIBRARY

BASIC PROTOCOL 7

SELECTIVE PRECIPITATION USING METALLIC AND POLYPHENOLIC HETEROPOLYANIONS

Under strongly acid conditions, inorganic and some organic strong anions—known as heteropolyanions—ably precipitate proteins. Inorganic anions used under acid conditions for this purpose include perchlorate, tungstate, phosphotungstate, molybdate, phosphomolybdate, tungstosilicate, and ferrocyanide. Inorganic ions (used under acid to neutral conditions) include sulfosalicylate, picrate, and diverse plant polyphenols and tannates (also see Critical Parameters).

Prior to overt precipitation, protein molecules under strongly acidic conditions are acid-expanded and remain soluble. When the heteropolyanions are introduced and allowed to bind, the protein molecules are forced back to a compact, poorly hydrated conformation. Molecular expansion and contraction of the protein in solution, which leads to precipitate formation, may be followed by biophysical tools (Fink, 1995). Driven further with additional heteropolyanions, such as perchlorate and tungstate in ~0.2% to 2% or 3% concentration, proteins coprecipitate with these anions in dense aggregates that easily settle or centrifuge down.

In some procedures for precipitating proteins, perchloric acid ($HClO_4$) is the precipitating agent of choice because it is ultraviolet-transparent above 250 nm. Perchloric acid precipitates whole protein molecules, but not their low-molecular-weight fragments—amino acids and oligopeptides. This is the basis for analysis with many proteolytic enzymes—at the end of the proteolytic cleavage assay, whole or intact proteins are precipitated out by a few percent $HClO_4$. Proteolytic fragments are left in the supernatant for subsequent A_{280} measurement, giving a rather direct measure of the amount of hydrolysis that occurred before adding the $HClO_4$.

BASIC PROTOCOL 8

SELECTIVE PRECIPITATION USING HYDROPHOBIC ION PAIRING (HIP) ENTANGLEMENT LIGANDS

Hydrophobic ion pairing (HIP) is coprecipitation of proteins using flexible hydrocarbon "tails" of alkane anions (detergents) that have their anion head groups bound in the target proteins. Figure 4.5.8 illustrates the composition of such a coprecipitate. Organic anions, especially sulfonates and sulfates, often bind strongly to proteins bearing cationic sites.

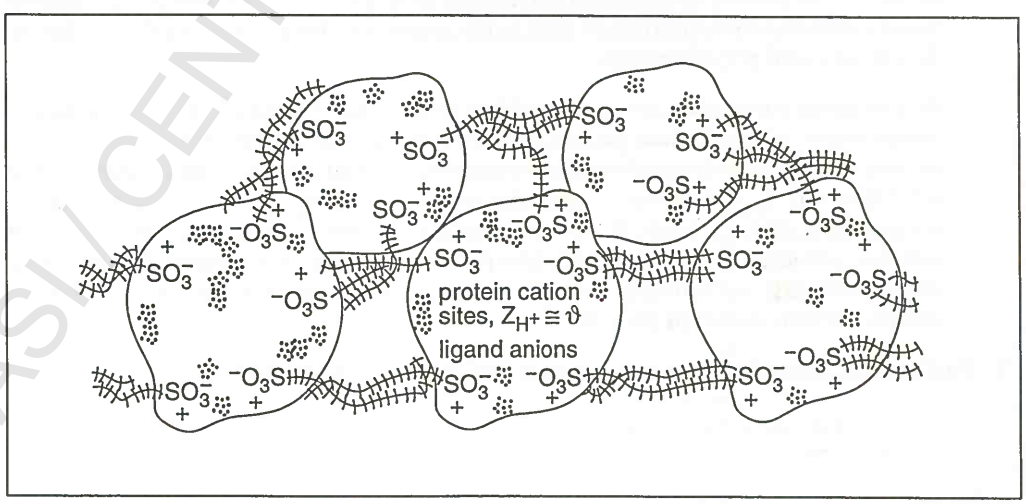


Figure 4.5.8 HIP coprecipitate. Strong anions (sulfate or sulfonate-bearing C_{10}–C_{14} alkane tails, e.g., dodecyl sulfate) bind to protein cationic sites forming ligand-protein complexes. Complexes draw together via tail-tail hydrophobic entanglement, aggregate, and coprecipitate. At maximum coprecipitating efficiency with ~10^{-5} M protein, the stoichiometric ratio of bound ligand anions (ν) is to cation side chains (Z_{H^+}) in the protein molecule is close to 1:1.

RCU IASI / CENTRAL UNIVERSITY LIBRARY

The organic alkane groups entangle and bind to each other in a manner similar to tail/tail association in micelles. Entanglement draws protein/ligand complexes together as shown in Figure 4.5.8. Such complexes go on to aggregate, then coprecipitate. Ordinary detergents such as dodecyl sulfate, (DDS^-) in correct protein/detergent ratios are able protein precipitants. Such ligands, especially detergent anions, need to be carefully regulated with regard to concentration. Suitable overall concentrations of precipitating detergents are usually 10^{-4} to 10^{-5} M when used with overall protein concentrations ranging from 0.01% to 0.001% (w/w) or 10^{-4} to 10^{-6} M protein. If suitable ligand concentrations are exceeded, the ligands go on to form micelles and solubilize proteins rather than precipitate them. Inside their optimum coprecipitation range with respect to total protein concentration, these ligands are rather generally effective towards many proteins.

Protein coprecipitation by HIP is frequently easy to reverse. The precipitate is redissolved in solvent with a pH ~2 or 3 units more alkaline than the coprecipitation pH. Detergent anions may be quantitatively stripped out with strong ion exchange resins, usually in the chloride form—e.g., Amberlite IRA-400Cl^- or Dowex-1Cl^-, or equivalent resins. Released proteins—e.g., enzymes in the supernatant—are then ready for assay.

SELECTIVE PRECIPITATION BY MATRIX-STACKING LIGAND COPRECIPITATION

BASIC PROTOCOL 9

Matrix-stacking ligands function (see Fig. 4.5.9) to draw protein molecules together in dense complexes that aggregate and coprecipitate protein. Ligand/ligand association forms a matrix host; protein molecules trapped in the matrix are guests. Occasionally, these ligands cocrystallize proteins and peptides (Conroy and Lovrien, 1992). Ligand organic tails bear rather rigid coplanar groups that stack and bind to one another π-face–π-face fashion, in a manner similar to stacking of aromatic bases in nucleic acid double helices. Tail-to-tail matrix association is reinforced by short alkane groups on the periphery of the tails—i.e., methyl, ethyl, and *t*-butyl substituents. The alkyl substituents lend hydrophobicity and promote water displacement, which helps drive tail-to-tail association. The structures of a few anionic ligands, are shown in Figure 4.5.10.

As with flexible-entanglement ligands (see Basic Protocol 8), the more rigid matrix-stacking ligands achieve maximal coprecipitation efficiency when ν ligands are bound per protein molecule with close to a 1:1 ratio of ν to Z_{H^+} —i.e., $\nu = \sim Z_{H^+}$, where Z_{H^+} = protein net cationic charge from H^+ titration of side chains. Hence coprecipitation depends on pH and how pH governs the protein charge, Z_{H^+}. Stacking and entanglement ligands in their most useful overall concentrations of 10^{-4} to 10^{-5} M often protect proteins as well as precipitate them. Such ligands tighten protein conformation, sometimes profoundly (Matulis and Lovrien, 1996). Protection often starts in solution before overt coprecipitation. The capacity to protect proteins against several kinds of degradation is an advantage of matrix-stacking ligand coprecipitation.

Two variables around which to design early protein coprecipitate experiments are illustrated in Figure 4.5.11. The following steps may be used for developing a matrix-ligand coprecipitation protocol.

Materials

Crude protein solution of interest, particle-free (see discussion of Clarification in Strategic Planning)
Potential ligands (Fig. 4.5.10; also see Aldrich catalog)
Appropriate buffers
Dowex-1Cl^- resin
Small test tubes or 2- to 3-ml plastic microcentrifuge tubes

BOULAS/CENTRAL CONNECTICUT STATE UNIVERSITY LIBRARY

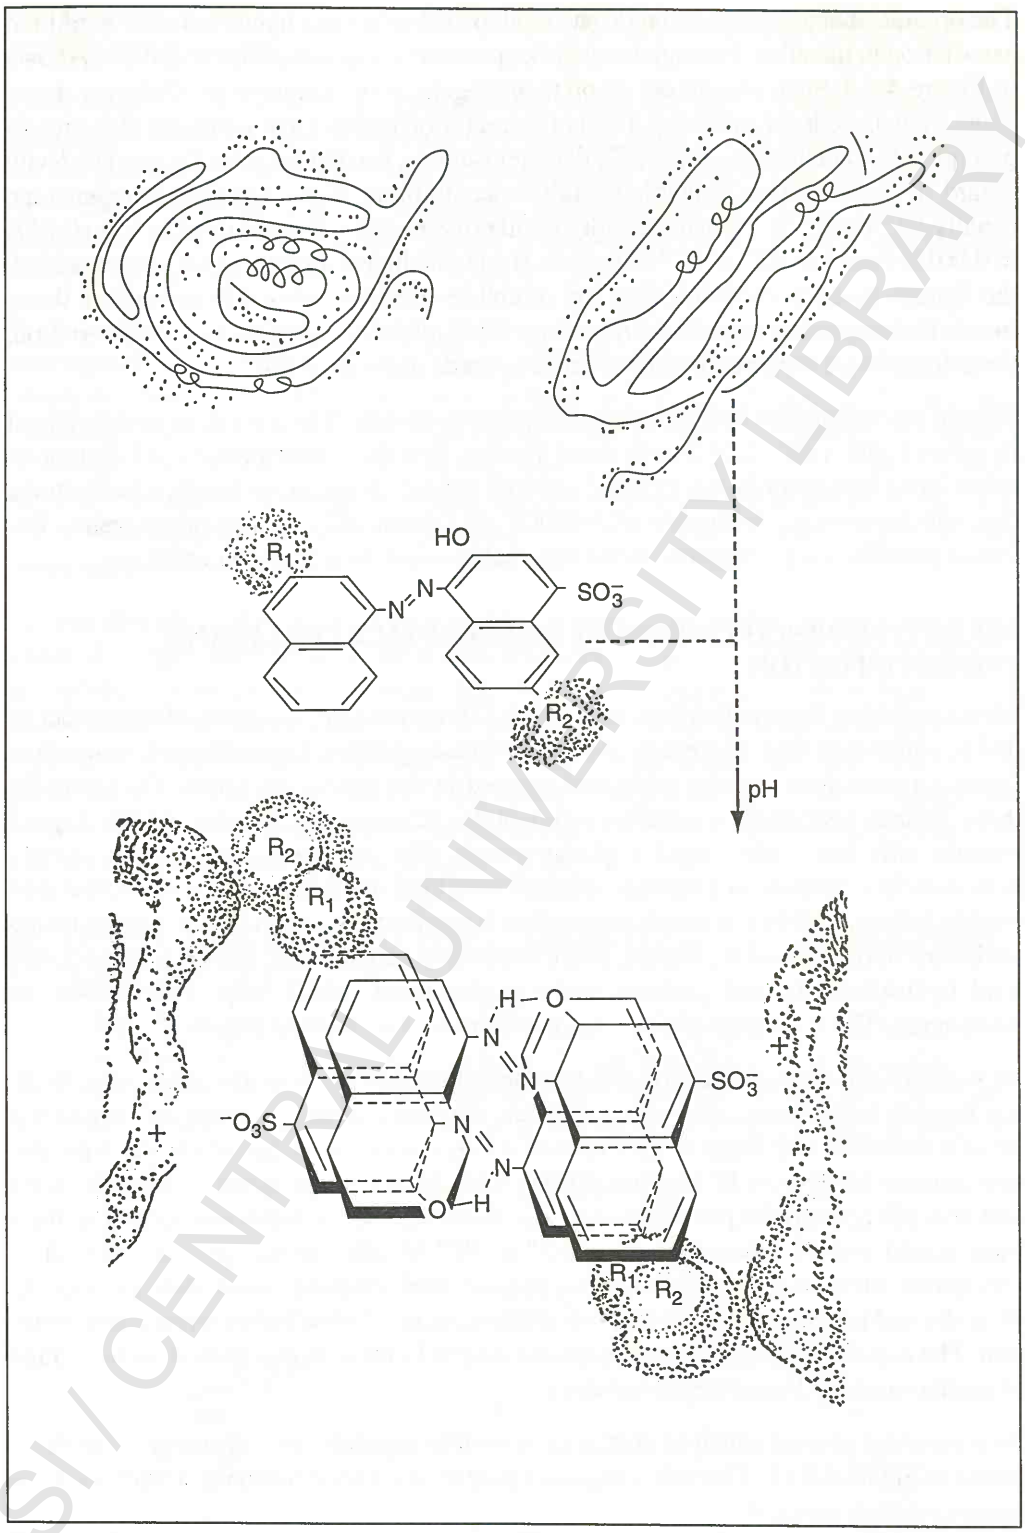

Figure 4.5.9 Molecular structure-function basis for matrix-stacking ligand coprecipitation of proteins. Protein molecules initially soluble in water and bearing a positive net charge attract strong anion (sulfonate) ligands. Such ligands associate via organic tail/organic tail stacking interaction, reinforced by alkane R-groups. Ligand/protein complexes are thus drawn together and coprecipitate out of solution.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

1. Set up grids of small test tubes or 2- to 3-ml plastic microcentrifuge tubes as in Figure 4.5.11. In each grid, vary two parameters versus one another to optimize coprecipitation—e.g., pH versus ligand concentration (with a fixed total protein concentration), pH versus kind of ligand, and other pairs of variables as described in Figure 4.5.11.

2. If possible, determine protein concentrations in samples to be precipitated (see *UNIT 3.4*).

   Usually if stacking and entanglement ligands are to function, proteins need be adjusted in pH in such a way that proteins of 20- to 60-kDa molecular weight carry a Z_{H^+} of ~15 to 40 net cationic charges. If protein molecular weights are unknown, assume ~40,000 Da, or assume the molecular weights typical of the kinds of proteins being worked with (e.g., common microbial and digestive proteases range from 20 to 35 kDa, and coagulation proteases from 50 to 75 kDa).

3. Determine isoionic point for the protein and optimal pH for precipitation.

   Expect to adjust the pH of some samples to between 2.5 and 5 if information from titration curves or amino acid analysis is not available for predicting Z_{H^+}. Preferably this is done

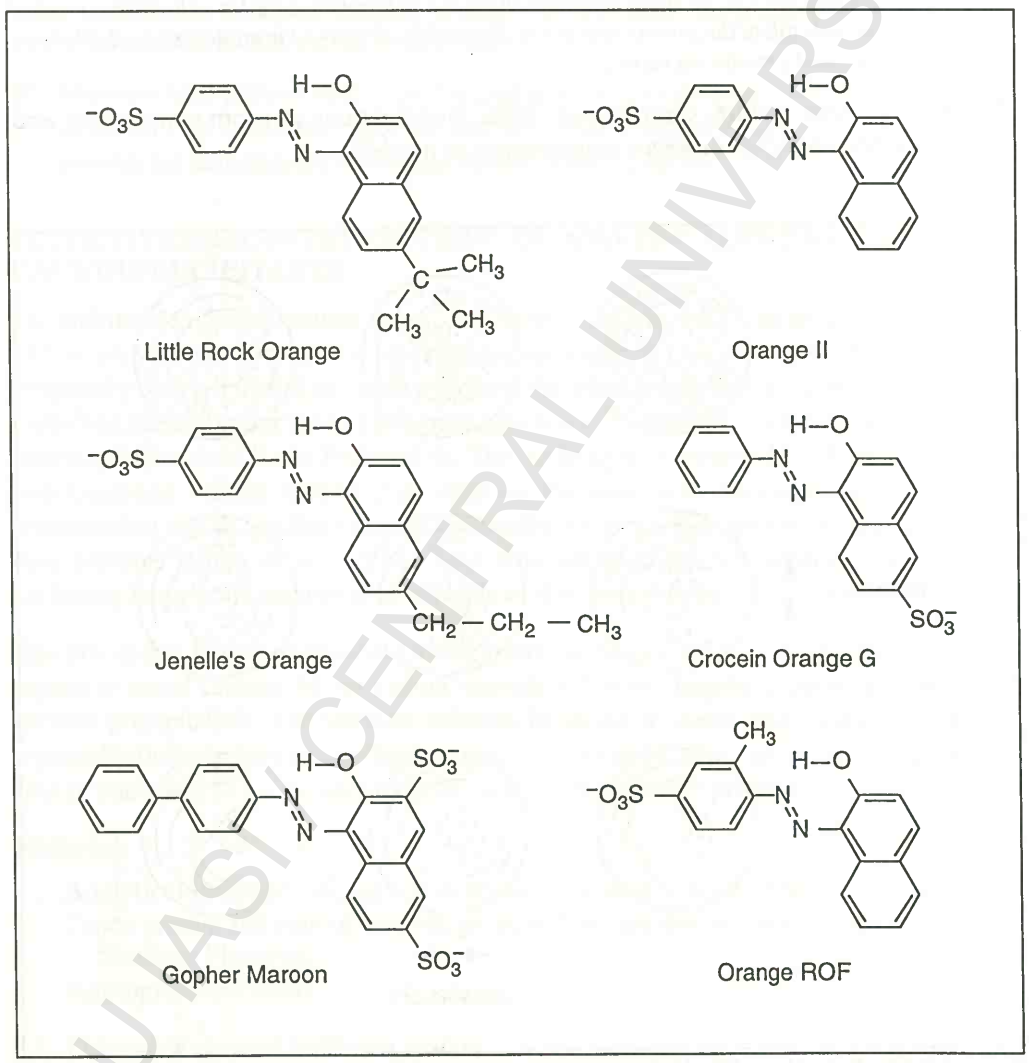

Figure 4.5.10 Anionic ligands synthesized with reinforcing alkane groups (Little Rock Orange and Jenelle's Orange) are very strong protein coprecipitants. Commercially available dye anions—Orange II, Crocein Orange G, and Orange ROF (available from Aldrich)—frequently are also efficient coprecipitating ligands for cationic proteins in pH ranges 2 to 4 units below the isoionic pH of the protein.

RU IASI CENTRAL UNIVERSITY LIBRARY

by direct acidification with ~0.01 M HCl accompanied by pH monitoring. Alternatively, buffers—e.g., glycine or formate buffers—are recommended. Do not adjust protein pH into acid regions before adding the ligands unless there is a need for protection by ligands in control experiments. If sought-for proteins are fragile at acid pH, ligands should be added before titrating the proteins to the lowered pH. Control (contrast) experiments may use the opposite sequence—i.e., acidify first and add ligand second. If there turns out to be much difference in the results obtained via the two sequences, protection of proteins from acid-pH denaturation is indicated.

4. Experiment with two or three ligands from Figure 4.5.10 or choose other potential ligands from among the azoaromatic sulfonate dyes listed in the Aldrich catalog. Prepare ligand stock solutions.

   Ligands are preferably dissolved in water or in dilute buffer at the running pH. Stay below the limit of ligand solubility, which can vary considerably, in making stock solutions. Upper solubility limits for a number of such ligands are 0.01 to 1 mM.

5. Add ligands from ligand stock solutions to protein sample in various volume ratios—e.g., ~1 vol stock solution to 2 vol protein solution and vice versa. Briefly vortex the mixtures.

   Extreme ratios—e.g., 10 vol of ligand solution to 1 vol protein samples—should be avoided as these will dilute the protein too much. If possible, arrange for modest mutual dilutions of ligand and proteins on mixing.

6. Optimize temperature, carrying out initial investigations at room temperature and proceeding to higher or lower temperatures as needed.

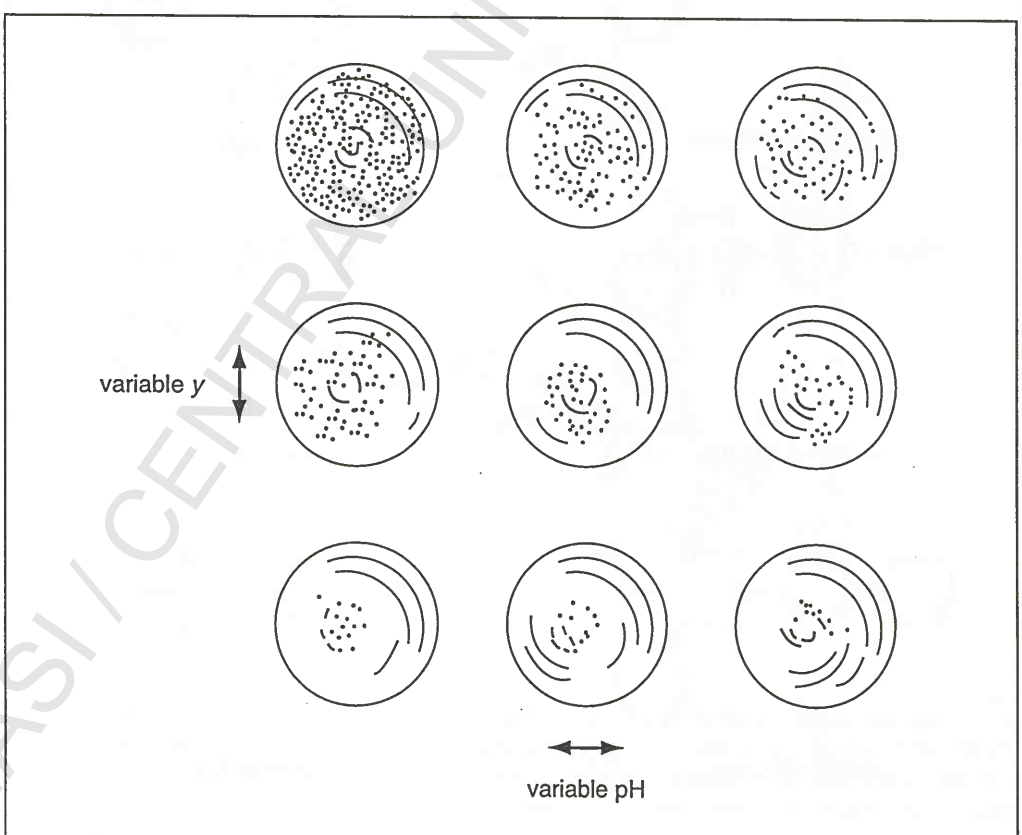

Figure 4.5.11 Sets of small test tubes or plastic microcentrifuge tubes, 2 to 3 ml in volume, may be used to to explore optimum conditions for matrix-ligand/protein mutual coprecipitation by varying pairs of important parameters. Five principal variables determining coprecipitation are: kind of ligand; ligand-protein ratio (*y*; often between 2 and 20); initial pH; temperature; and concentrations of auxiliary coprecipitating agents such as Zn^{2+} (10^{-3} to 10^{-4} M).

PCU IASI / CENTRAL UNIVERSITY LIBRARY

7. Determine rate of precipitation giving the optimal yield.

Matrix-ligand coprecipitation is sometimes rate-limited when protein concentrations start from <0.1% (w/v). If this is the case, incubate ligand/protein mixtures for a few hours. Rather often, coprecipitation occurs rapidly; however, to avoid including unwanted compounds in coprecipitates, do not drive the coprecipitation reaction too rapidly (if possible).

8. Collect coprecipitates by centrifugation at 5 to 50 × *g*. Perform bioassay of the coprecipitates and, if necessary, of the supernatant for the protein of interest.

In some systems, e.g., peroxidase isolations from crudes, myriad unwanted proteins precipitate out first and the peroxidase enzyme is left in the supernatant.

9. Redissolve coprecipitates by shifting pH upward with 0.1 M acetate, imidazole, or phosphate buffers, pH 5 to 7. Add ~100 mg of Dowex-1Cl$^-$ resin and incubate 5 to 15 min with gentle shaking to trap the anionic ligands. Monitor the completeness of trapping via the color of the matrix ligand.

Approximately 100 mg of resin per milliliter of the higher-pH redissolving buffer provides a good excess of trapping capacity. See Basic Protocol 2 for discussion of the capacities of anion exchange resins. Dowex-1 resins have ~1 meq of capacity per ml (wet volume) of resin beads. Complete trapping is easily followed from matrix ligand's color. Released proteins in solution should be colorless.

10. Measure total protein (and total released activity if an enzymatic or other bioassay is available) to determine specific activity, total recovered activity, and recovered protein for comparison to samples before coprecipitation.

SELECTIVE PRECIPITATION USING DI- AND TRIVALENT METAL CATION PRECIPITANTS

BASIC PROTOCOL 10

Di- and trivalent metal cations—e.g., Zn^{2+}, Mn^{2+}, Ca^{2+}, and Al^{3+} (general symbol M^{2+} or M^{3+})—provide two means for precipitating proteins: (1) they may act directly, or (2) frequently they are useful as auxiliary agents for other precipitation methods such as the crowding method using neutral polymers (see Basic Protocol 5) or matrix-stacking ligand coprecipitation (see Basic Protocol 9). This technique is reviewed by Rothstein (1994) and Gurd and Wilcox (1956). Zinc ions are the ions most commonly used for direct precipitation and as auxiliary agents, especially when working with plasma and coagulation proteins (Cohn et al., 1950). Zinc ions are required for insulin crystallization, including large-scale industrial production of this polypeptide.

The discussion below represents a small sector of the landscape of chemical behavior in regard to metal cations. Metal cations provide a diverse, largely undeveloped means of protein precipitation. The intrinsic solution behavior of metal ions (without proteins), especially their chelation-coordination reactions, must be taken into account for application of such ions to the development of protein precipitation methods.

Materials

Analytical Reagent (AR)-grade metal salts (generally as chloride or nitrate)
Crude protein solution of interest, particle-free (see discussion of Clarification in Strategic Planning)
Appropriate buffer(s)

1. Determine optimal buffering system.

The precipitation system may be buffered in two respects: (1) toward H^+ ions and pH in the conventional way and (2) also with respect to metal ions, using metal ion buffers which are coordinating and chelating agents (Perrin and Dempsey, 1974). A number of com-

BOURSE CENTRAL UNIVERSITY LIBRARY

pounds—e.g., EDTA, citrate, and several amino acids—can serve both buffering purposes. Evidence that compounds serve as one or both of these types of buffer is that pH dependency and/or metal ion concentration dependency of protein precipitation is rather sharply dependent on the kind of buffering compound. Zwitterionic buffers such as HEPES may be useful for controlling pH because they have much less tendency to bind or coordinate with metal ions than conventional Sorenson buffers (e.g., phosphate). Because proteins are also buffers, their self-buffering action may suffice to control pH if present in concentrations ≥0.3%.

2. Select an appropriate metal cation and precipitate protein.

Di- and trivalent metal cations (M^{2+} and M^{3+}) are vigorously precipitated by salts and inorganic buffer anions, which are present in protein extracts and samples at various stages of isolation. Sulfate (from salting out; see Basic Protocol 1 and Alternate Protocol) powerfully precipitates Ca^{2+} as $CaSO_4$. Solubilities of <100 mg/ml or even <10 mg/100 ml are seen with $Zn(NH_4)PO_4$, $Mn_3(PO_4)_2{\cdot}7H_2O$, $MnCO_3$, $Mg(NH_4)PO_4{\cdot}6H_2O$, $MgCO_3$, $CaCO_3$, and a number of calcium phosphates. Sulfates and carbonates of Ba^{2+} are extremely insoluble (Hogness and Johnson, 1954). Before committing a metal ion as a precipitating agent: (1) review general behavior with respect to precipitability by buffer and salt anions in the protein solvent; (2) carry out control experiments with protein-free samples to find if the solvent(s) are likely to produce massive precipitates of simple inorganic compounds with the metal ion; and (3) arrange to remove interfering anions if the anions are in concentrations ≥0.05 M or if concentrations of ions such as $SO_{4^{-2}}$ and $CO_{3^{-2}}$ re <0.05 M.

Trivalent metal ions such as Al^{3+} and Fe^{3+} form a complicated series of oxo-, hydrate, and hydroxylated species in water. They go on to form insoluble hydroxides (solubility products 10^{-30} to 10^{-40}; Hogness and Johnson, 1954), at neutral and even somewhat acidic pH. Metal cations of this kind are interesting protein precipitants (Gurd and Wilcox, 1956). However, instead of complexing with protein molecules, they may form very insoluble hydroxyl gels and flocculate proteins by adsorption on the gels at pH ≥5. Hence development of protein precipitation with such cations may need be to confined to rather acidic pH regions.

It is not necessarily a disadvantage if low-molecular-weight salts or other solvent components precipitate M^{2+} first, before proteins are precipitated. Inorganic precipitates of sulfate, phosphate, and carbonate may form first. These can then be centrifuged away, whereupon more metal ions are added to bring down the sought-for protein, in a second stage of precipitation. Total protein measurements (UNIT 3.4) are used to locate the starting point for protein precipitation by the metal ions.

3. Analyze precipitate.

Analysis of metal content of coprecipitates and their supernatants is useful for characterizing products and following how variations in procedures determine product composition. The most generally accessible methods are spectrophotometric, using color-developing reagents capable of quantitating metal cations at 10^{-4} to 10^{-5} M concentrations (Sandell and Onishi, 1978). Figure 4.5.12 shows a calibration curve for Zn^{2+} analysis using pyridylazoresorcinol (PAR; Aldrich). The optimal pH for use of PAR is ~7 (Cheng et al., 1992) in HEPES or other nonchelating buffer. 0.1 mM PAR is prepared in 0.05 M HEPES buffer, pH 7.0, then dilutions of Zn^{2+} (as zinc acetate) are prepared in the same buffer at various concentrations ranging from 5 to 30 μM. The PAR reagent may be made up as a 1 mM stock solution and diluted 10-fold to provide the working reagent at 0.1 mM. Spectrophotometric samples are made by mixing 1.0 ml of 0.1 mM PAR with 1.0 ml of each of the Zn^{2+} dilutions. A_{495} is then measured versus a reference of equal PAR concentration without zinc. The slope of the plot in Figure 4.5.12 is the molar extinction coefficient, $\varepsilon_{495} = 4.5 \times 10^4\ M^{-1}\ cm^{-1}$. An example of Zn^{2+} release from a zinc enzyme monitored by PAR color development is given in Hunt et al. (1985). Zinc analysis is a criterion for the identification and purity of insulin.

PCU IASI CENTRE UNIVERSITY LIBRARY

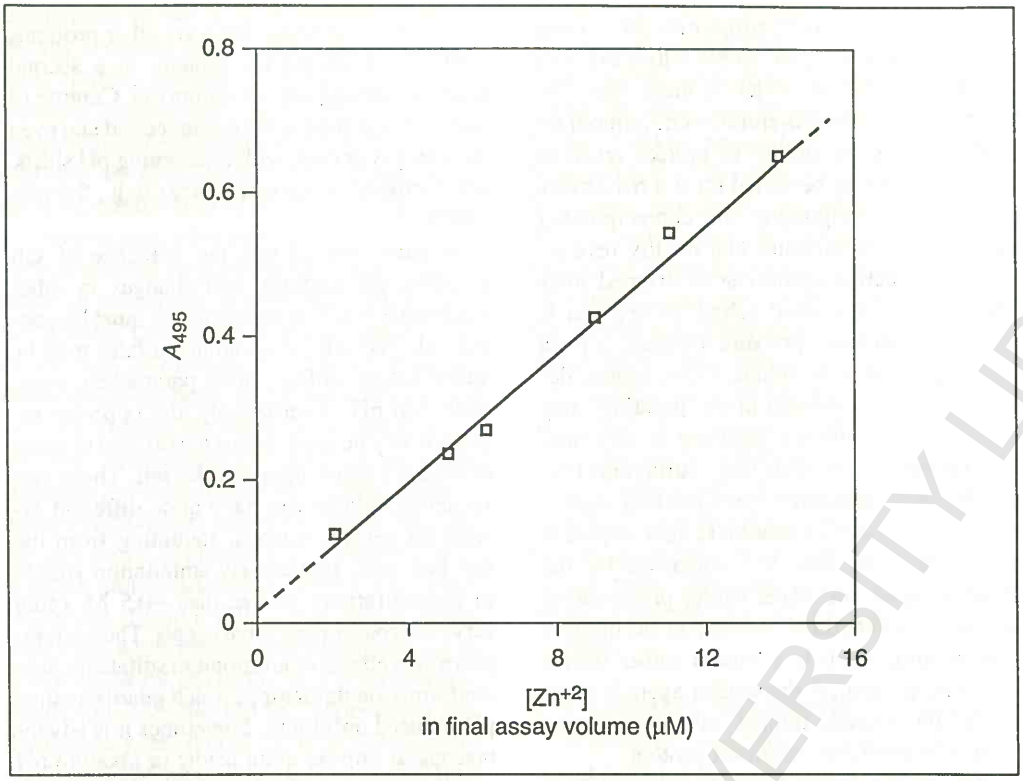

Figure 4.5.12 Calibration plot for zinc ion spectrophotometric analysis using pyridylazoresorcinol reagent.

4. Remove metal ions from precipitate.

   Metal ions may be removed from protein precipitates via cation-exchange resin trapping, or by treating precipitates with a buffer at a pH at which it is expected to dissolve. It is preferable to mix the precipitate with a release buffer first to see if in fact it does dissolve, then test the resin-bead exchanger afterwards. Trapping resins in the Na^+ or K^+ form may be tested; conventional cation resins such as Amberlite IR-120Na^+ usually give adequate results. A specialty chelating resin—Chelex 100 exchange beads (Bio-Rad)—may also be used. The exchange capacities of such resins are 1.8 and 0.4 meq (milliequivalents) per milliliter of wet resin. The resins should not be used in great excess (i.e., >5× resin equivalents per estimated equivalent of metal to be removed) because such resins may also adsorb proteins. Exchange of metal ions out of precipitates may be accelerated by conventional soluble chelating agents (e.g., 10^{-4} M EDTA) or by amino acids such as aspartic acid in the case of Zn^{2+} (Fiabane and Williams, 1977).

5. Perform bioassay for protein of interest.

COMMENTARY

Background Information

In practice, most protein-precipitating agents and methods yield a variety of different products depending upon conditions such as pH, metal ions present in the solution, and/or presence of cosolvents. Many "precipitates" are actually coprecipitates in which molecules of the precipitating agent remain bound to the proteins. How much precipitating agent or ligand becomes bound and thus coprecipitated usually remains unclear until the coprecipitate is analyzed. Precipitation and coprecipitation are most important in "upstream" stages of protein isolation—for crude, dilute, solutions in large volumes up to several liters. However, precipitation is sometimes useful downstream also, as it reduces volume—e.g., excess solvent and buffers may be removed from chromatographic eluates via this technique. Sometimes it is an efficient strategy to precipitate unwanted proteins in the first stages of purification and then capture the sought-for protein in a second precipitation step later.

Some precipitation methods are old, and

BU / OEP / GENERAL UNIVERSITY LIBRARY

some have been developed more recently. Some of the old methods, particularly salting out with ammonium sulfate (which is more than 130 years old), remain as useful as ever. Ammonium sulfate offers the ability to protect sensitive proteins and may be scaled up at a reasonable cost. Some precipitating and coprecipitating agents yield precipitates that readily reverse. Reversibly acting agents can be stripped away later—e.g., ammonium sulfate salting out is reversed by dialysis, pressure filtration, or resin exchange to remove sulfate. Other agents, despite their great powers in precipitating, may be difficult to remove completely, or may catalyze damage to proteins (e.g., sulfhydryl oxidation). Consequently, precipitating agents must be evaluated in relation to later steps that may have to be used to compensate for the disadvantages that some strong precipitating agents carry with them. Sometimes the optimal precipitating agent is a weaker rather than a very strong agent, if the weaker agent is more easily dissociated, trapped out, or dialyzed away to release the sought-for protein.

Besides the agents and individual methods listed in Table 4.5.1, combinations of methods are frequently advantageous. For example, sometimes it is helpful to add modest concentrations of Zn^{2+} to proteins that one is trying to precipitate by another method. Another precipitation technique, TPP (see Basic Protocol 4), is also a "hybrid"—a combination of organic cosolvent precipitation and sulfate kosmotropic precipitation. Precipitation and coprecipitation are often quite protective of proteins, especially in salting-out techniques. However, whether or not protection is achieved frequently depends on the sequence of steps used in each protocol. For example, if salting out or coprecipitation with a particular ligand needs to be carried out at a pH very different from the starting point, a choice must be made between shifting pH first and then adding salt, or alternatively adding salt or ligand first and then readjusting pH. The latter is usually best choice in terms of protecting the protein.

Critical Parameters and Troubleshooting

Salting out

In the simplest version of salting out, desired proteins are precipitated relatively early and the supernatant is set aside or discarded. In this case, unwanted proteins are often left in the supernatant. The supernatant may, however, be readjusted in pH, increased in salt concentration, or both, to bring down yet other proteins, perhaps the sought-for protein, in a second stage or "second cut" of salting out. Capture of sought-for protein activities in second and even third stages or cuts, with intervening pH shifts, are discussed in various sources (e.g., Scopes, 1987).

In each step, or cut, the sequence of salt addition, pH shifting, and changes in other parameters (such as temperature) must be considered. The salt (ammonium sulfate) may be added before shifting other parameters, especially the pH. Alternatively, the opposite sequence may be used: adjust the pH first to some desired set point, then add the salt. These two sequence options can have quite different effects for several reasons, stemming from the fact that salts, particularly ammonium sulfate in concentrations greater than ~0.5 M, often serve as protein-protective agents. The protein-protective effects of ammonium sulfate include conformation tightening, which guards against pH-induced unfolding. Sometimes it is advantageous to impose quite acidic or alkaline pH extremes or a thermal shock, to first precipitate unwanted, denatured proteins, and leave sought-for proteins in the supernatant. However, the amount of salt and when to add it are variables; these need attention in weaving the optimum path for salting out.

Several treatises and textbooks present tables, formulas, and nomograms for relating percent saturation, molar concentration, weight of ammonium sulfate to be added, and dilution factors that are useful for increasing or decreasing amounts of ammonium sulfate so as to arrive at prescribed concentrations of the salt. The numerical relationships are mostly cited for 0° to 30°C, although the solubility of ammonium sulfate in water changes little. Saturated ammonium sulfate in water is close to 4.1 M. Two relationships cited by Scopes (1987) give the number of grams (g) to be added to a liter of solution at 20°C for shifting molarity (M) and percent saturation (S). The first of these equations is for shifting to a molarity M_2 starting at molarity M_1:

$$g = \frac{553(M_2 - M_1)}{4.05 - 0.3M_2}$$

The second equation is for shifting to a percent saturation S_2 starting at percent saturation S_1.

$$g = \frac{553(S_2 - S_1)}{100 - 0.3S_2}$$

These relationships pertain to solutions of

PCU IASRI LIBRARY

ammonium sulfate in water. Proteins that are already in diverse buffers and that contain other salts, in unknown concentrations, throw off the accuracy of nomograms and formulas for shifting saturation percentages and molarities. Nevertheless, these are useful for estimating added salt concentrations to be used and for reporting.

Neutral salts other than ammonium sulfate, such as sodium or potassium chloride, may be tested in attempting to precipitate the sought-for protein (and later in attempting to split excess salt away—i.e., reverse the process). However, ammonium sulfate is usually the best primary choice, not because of tradition but because the sulfate anion, SO_4^{-2}, is one of the strongest yet most benign Hofmeister kosmotropes (*UNIT 8.4*) over nearly the whole "biological" pH range, approximately from pH 2 to 10 (Collins and Washabaugh, 1985). The orthophosphate dianion, HPO_4^{-2} is also a strong, inexpensive kosmotrope and salting-out agent. However the pK of $H_2PO_4^-$ is 7.2; accordingly, below pH ~6.5 the $H_2PO_4^-$ monoanion predominates even though it is a considerably weaker kosmotrope. Other anions such as fluoride, F^-, are good kosmotropes but are very toxic. For a combination of desirable properties, including least expense, the sulfate systems remain the most convenient, reliable, and most tested. One disadvantage of sulfate arises in the case of proteins requiring calcium ion, Ca^{2+}. Because calcium sulfate and calcium phosphate are extremely insoluble, both SO_4^{-2} and HPO_4^{-2} precipitate Ca^{2+}. Hence, for calcium-requiring proteins, salting out may have to be developed with salts other than sulfates—e.g., acetates are a possibility.

Isoionic precipitation

Amberlite resins IR-120 (a cation exchanger) and IRA-400 (an anion exchanger), in the form of 6% or 8% cross-linked beads, are the basis of the original Dintzis mixed-bed exchangers. The equivalent Dowex exchangers, Dowex 1 and Dowex 50 series, in the form of 6% to 8% cross-linked resins, serve equally well but are not superior.

Anion and cation exchangers have differing exchange capacities per settled milliliter of wet resin. IR-120H^+ has ~1.8 meq/ml of capacity, and IRA-400OH^- has ~1.2 meq/ml. Accordingly each 100 ml of mixed exchanger may be made by mixing 40 ml of the cation exchanger in the H^+ form with 60 ml of anion exchanger in the OH^- form, a volume ratio inversely proportional to their intrinsic exchange capacity ratio. Mixed-bed exchangers may be stored in the cold (do not freeze them) for long periods without self-neutralization.

Mixed-bed exchangers, such as the MB-1 Amberlite series, may be purchased premixed. However it is recommended that the exchanger be mixed in the laboratory to ensure that resins have been "exercised" (see Basic Protocol 2, steps 2 and 3) and leached of any polymer hydrolysis products. Anion exchangers based on various quaternary amines are especially susceptible to self-hydrolysis (detectable by an amine odor) upon storage in the OH^- form. Commercial ready-mixed bed resins usually incorporate dye chromogens (acid-base indicator molecules), which show (by a blue to amber color change) when their capacity has been titrated. Such resins may be usable with some protein molecules, but if there is any leaching out of resin materials, the eluants will be strongly colored, indicating contamination of proteins.

Two-carbon organic cosolvent precipitation

In Basic Protocol 3, no general criterion can be put forth for choosing between acetone and ethanol, for deciding how pH should be adjusted versus the isoionic point of the protein, or for determining the exact salt concentration to be used. There exists a large body of literature describing empirical, experimental means for C_2 cosolvent–based isolation of dozens of proteins. A few guidelines may be useful. Ethanol was the C_2 cosolvent used for the isolation of most blood-plasma proteins. Many respiratory enzymes have been isolated with a step involving an acetone cosolvent. In systems where lipids and triglycerides are troublesome, many workers have used acetone cosolvents, sometimes at nearly 100% acetone, because acetone and acetone-water mixtures extract lipid materials. Acetone in such applications functions as an extractant as well as a protein precipitating agent. Proteins and whole-tissue agglomerates that have been rendered nearly lipid-free by acetone, then lyophilized, are referred to as "acetone powders."

A review with many references was recently written by Rothstein (1994), which includes discussion of the seminal papers by Cohn and coworkers. With a number of proteins, a complex relationship exists between salts, the C_2 organic cosolvents, the proteins, (which bind salts to some extent), and the pH. These parameters operate to make organic cosolvent precipitation quite empirical.

Methanol and the two-carbon organic cosolvents appear to be able to penetrate protein

PRINCETON UNIVERSITY LIBRARY

molecules and compete with water for sites inside. However C_4 and larger cosolvents are largely excluded from the inside of proteins if the proteins are kept compact and folded. Accordingly, it is unlikely that the larger cosolvent molecules, such as C_4 alcohols, behave congruently with the C_1 and C_2 cosolvents for most proteins.

C_4 and C_5 organic cosolvent precipitation

Some C_4 organic cosolvents, particularly *t*-butanol and *n*-butanol, are able precipitating and extracting agents for proteins. They are useful in "upstream" stages of isolation, starting with crude solutions. They are variously used in combination with osmolytes and salting-out agents such as ammonium sulfate. Conditions are adjusted in such a way that separated layers of cosolvent are obtained, along with an aqueous layer and a layer of precipitated protein. The separated liquid layers act as extraction and partitioning systems as well as protein precipitation systems. Precipitated proteins usually appear at the interface between liquid layers. Because some of the C_4 and C_5 cosolvents act either as kosmotropes or in parallel to kosmotropes like the sulfate anion, these cosolvents frequently are protective of aqueous proteins even at normal temperatures, 20° to 30°C. They induce protein-molecule conformation tightening, from which the protein-molecule protection partly originates. The similarity between sulfate interaction with proteins and C_4/C_5 cosolvent interaction with proteins does not, however, have the same origin. Sulfate exerts electrostatic forces toward many proteins (Chakrabarti, 1993), whereas *t*-butanol exerts much less electrostatic-based interaction, perhaps none at all. A rough model of the effect of the *t*-butanol cosolvent is that it behaves like a neutral osmolyte in water.

It is not always strictly necessary to choose *t*-butanol as the cosolvent. However, *t*-butanol has some advantages. First, it is relatively inexpensive. Only ~0.3 to 0.5 ml of *t*-butanol is required per milliliter of starting aqueous protein solution, after the optimal amount of salt has been added. When *t*-butanol is used, smaller amounts of ammonium sulfate are usually required for a given precipitation, relative to the amounts needed in conventional salting out. Second, *t*-butanol is much less volatile than C_2 cosolvents, especially in water-dominated systems. Hence it poses less of a fire hazard and less hazard from inhalation. Third, *t*-butanol is, in general, far less denaturing at 20° to 30°C temperatures than C_2 cosolvents. Fourth, *t*-butanol behaves similarly to kosmotropes and osmolytes, protecting proteins. Finally, the extractive and partitioning capacities of three-phase partitioning (TPP) using C_4 and C_5 organic cosolvents (see Fig. 4.5.6) tend to remove pigments, lipids, and amino acids from proteins.

C_4 and C_5 organic cosolvents in the aqueous phase produced by techniques like TPP exert themselves as osmolytes and crowding agents, up to a point, when they reach concentrations of several percent. However, the main differences between the C_4/C_5 organic compounds (of the types discussed here—e.g., butanols and pentanols) and water-soluble osmolytes such as sugars are: (1) osmolytes like sugars and amino acids tend not to form a separate organic phase that goes on to act as an extraction phase for lipids, pigments, and other nonprotein material, whereas the butanols and pentanols do; and (2) hydrocarbonaceous C_4 and C_5 compounds bind to some extent to proteins that have a high degree of nonpolar, hydrophobic character. This latter property causes such proteins to position themselves as illustrated in Figure 4.5.6, floating above the aqueous layer. When the protein precipitate (i.e., coprecipitate) is redissolved in buffer with low salt, then shifted away from the precipitative pH (usually upward ~2 to 3 pH units), in most instances the C_4/C_5 compounds dissociate. In contrast, conventional osmolytes, especially sugar, tend not to bind to proteins.

In some versions of TPP, the system is operated in two stages. In the first stage, the precipitate containing unwanted proteins that forms at the initial pH is discarded. The aqueous phase is then shifted in pH, and/or more salt is added, giving a second precipitate containing the sought-for protein. In the example described in Lovrien et al. (1987), the enzyme α-amylase is isolated in this way. Many sorts of variations can be made in pH, salt concentration, and other parameters.

Protein-exclusion and crowding agents

Exclusion agents and osmolytes have high affinities for water and compete with proteins in solution for water. The crowding action, aided by any degree of affinity of protein molecules for one another (protein-to-protein association) promotes protein precipitation. Thermodynamic pushing occurs because hostile environments imposed on proteins in osmolytes and and in crowded solution raises protein chemical potential in a positive direction. This is then relieved by protein precipitation, which

PCU IAS LIBRARY

enables protein molecules to exist with lowered chemical potential.

Crowding and exclusion agents frequently act upon conformationally motile (loose), water-penetrated proteins before overt precipitation. Conformationally loose protein molecules are also "squeezed" on by these agents, promoting protein molecule tightening and sometimes promoting an ordered protein conformation. Proteins thus "squeezed on" often become protected, sometimes dramatically. Moreover if their conformation is forced into good order, protein molecules may crystallize instead of simply being precipitated in amorphous form. Thus, the osmolyte MPD (2-methyl-2,4-pentanediol) is often used with success for protein crystallization. MPD crowds, excludes, and squeezes to push proteins into a narrow or even single conformation necessary for arriving at the crystalline state.

As a general rule, osmolytes and crowding agents do not bind strongly to proteins. Hence, ideally, precipitated proteins are free of such agents. However in fact, some agents bind rather weakly, and appear in the precipitate (which is in fact a coprecipitate). Accordingly, selection of the agent may depend on the ease or difficulty of removing trapped agent from protein precipitates if in fact the desired redissolved protein needs be stripped of precipitating agent.

Neutral polymers such as polyethylene glycol (PEG) and dextran, which do not affect electric charge, might be expected to act toward proteins independently of electrostatic parameters such as protein net charge and salt concentration. However, the opposite often occurs: i.e., buffer, salt, and pH-dependent protein charge frequently sharpen and either greatly enhance or sometimes depress protein precipitation via PEG. Salts in concentrations quite below normal kosmotropic concentrations—i.e., 0.01 to 0.5 M salts—have a large influence, decreasing chymotrypsin solubility and increasing its precipitation by PEG (Miekka and Ingham, 1978). In other examples, chaotropic anions and "Hofmeister-neutral" anions (e.g., chloride) increase protein solubility and depress precipitation. Readers may profit by consulting some of the papers referred to here, particularly to Miekka and Ingham (1978) to review how large and variable these "electrostatic" effects may be.

Neutral polymers, acting as steric-exclusion precipitants, and the monomers of such polymers, acting as osmolytes, are far from equivalent in protein-precipitating power when used in equal concentrations. The polymers appear to be considerably most effective. For example, Laurent (1963) investigated dextran polymer and its monomer glucose as precipitants for albumin and fibrinogen. Dextran polymer considerably outstripped glucose in precipitation power when each reagent was used at a concentration of ~0% to 10% (w/v). On the other hand, concentrations of proteins for achieving protein precipitation using neutral polymers usually must be from 1% to 5% (w/v). Hence the neutral polymers are considerably less sensitive and less effective at low protein concentrations than some of the other methods discussed in this unit—e.g., the matrix-stacked ligand technique (see Basic Protocol 9 and discussion below).

Neutral polymers are equivalent to neutral polymers used in aqueous two-phase partitioning (Walter and Johansson, 1994) and as "precipitants" in protein crystallization (McPherson, 1982). PEG is the dominant polymer used in two-phase partitioning and as a precipitant for protein crystallization. PEG polymers in several molecular-weight ranges—low, medium, and high—are available from Sigma and other suppliers. Choice of PEG molecular weights must be balanced between two considerations. Higher-molecular-weight polymers tend to be more effective precipitants for some proteins (i.e., able to precipitate albumins out of solution in ~5% to 15% PEG concentration ranges; Atha and Ingham, 1981). Lower-molecular-weight PEG polymers of molecular weight <3000 to 4000 generally must be used in 20% to 50% concentrations to effectively precipitate a number of proteins that have been studied. However, the practical problem of ridding precipitated proteins of trapped PEG polymers is eased with low-molecular-weight PEGs because they dialyze away relatively easily. Proteins generally are more sensitive to precipitation by high-molecular-weight PEGs than low molecular-weight-PEGs, frequently precipitating, if indeed they do so, in 3% to 20% concentrations of large PEGs (molecular weight greater than ~4000; Atha and Ingham, 1981). The downside of high-molecular-weight PEGs is that, if trapped, these PEGs become difficult to separate from coprecipitated proteins by simple dialysis. Also, high-molecular-weight PEG solutions tend to be quite viscous, whereas oligomeric low-molecular-weight PEGs are easier to handle and mix.

Alkane ether polymers (trade name Ucon; Union Carbide; see *SUPPLIERS APPENDIX*), which are copolymers of ethylene and propylene ox-

POLYCENTRAL LIBRARY

ide related to PEGs, go into and out of solution with marked temperature dependency (i.e., they "phase-separate"; Albertsson and Tjerneld, 1994). Accordingly, with the use of such polymers, manipulation of temperatures in initial precipitation and in redissolving protein precipitates may afford means for balancing these two problems.

Synthetic and semisynthetic polyelectrolytes

Polyelectrolytes have been synthesized as copolymers with nonionic groups to help alleviate problems that arise with homopolymers such as polyacrylic and polymethacrylic acid. The latter homopolyelectrolytes, when ionized, are so strongly coprecipitating that they are often poorly selective. Hence, copolymers of acrylic acid and methacrylic acid with a nonionic methylmethacrylate ester side function as agents with softened coprecipitating power but increased selectivity. A series of copolymers of this type, with varying ratios of ionic and nonionic groups, are named "Eudragit" agents, and are available commercially from Rohm GmbH (see *SUPPLIERS APPENDIX* and Mattiasson and Kaul, 1994). Copolymerization of two and even three separate vinyl monomers provide polyampholytes of myriad kinds, differing in ratios of vinyl monomers. Synthetic polyampholytes take on net positive, net negative, or zero charge, depending on the pH (like proteins, which are also polyampholytes). The advantage of such compounds is that after coprecipitating proteins, the synthetic polyampholyte can be split away from the protein by adjusting the pH of the mixture to the isoionic pH of the polyampholyte, which will precipitate it separately (Patrickios et al., 1994). Many of the polymers that have been discussed so far—e.g., carboxymethylcellulose and polymethacrylic acid anion—are negatively charged above the pK of their side-chain carboxyl groups, ~pH 5. Such polymers should primarily be used for precipitating proteins that are cationic—i.e., in pH ranges below the target protein's isoelectric point. However, it may be necessary to experiment with synthetic polyelectrolytes which are cations and which are therefore primarily aimed at precipitating anionic proteins in pH ranges impractical for synthetic polyanions. The most common, readily available neutral-cationic synthetic polyelectrolyte of this type is polyethyleneimine (PEI). The H^+-titratable nitrogen groups of PEI are integral parts of its backbone, not relegated to side chains. PEI is very basic and exists as a polycation over a very wide range of pH. PEI is also a powerful coprecipitating agent for proteins. Table 4.5.2 lists a small number of polyelectrolytes, several of which are sold by Aldrich and Sigma. References in Table 4.5.2 should enable the reader to survey conditions used for coprecipitation of various enzymes.

Metallic and polyphenolic heteropolyanions

There is considerable variability but lack of much quantitative information concerning recovery and bioactivity measurements of most proteins that have been precipitated with heteropolyanions, in cases where their activities must be recovered. The great acidity and also the oxidizing power of some of these agents—e.g., $HClO_4$—tends to seriously denature many proteins. Deamidation of proteins sometimes follows strong acidification, as well as unwanted hydrolysis and conformational unfolding. However, weaker acids such as tannic acid (a mixture of several phenolic products) are less denaturing, and yield intact active enzymes and other proteins after tannate precipitation at neutral pH. Accordingly, choosing among heteropolyanion precipitation agents depends on the use to which the protein precipitates are to be put. For very rapid, complete precipitation of unwanted proteins down to ~50 µg/ml (Bensadoun and Weinstein, 1976), in cases where destruction of proteins is acceptable, $HClO_4$ in 1% to 5% concentration is used. Picric acid is almost equally effective, but it is highly colored and hence interferes in analytic procedures requiring spectrophotometric measurement. As with polyelectrolyte precipitation, which agent to use may depend on the ease versus difficulty of removing such agents from proteins after coprecipitation.

Examples of precipitation of diverse proteins by heteropoly anions at mildly acidic pH (i.e., pH 4 to 6) are described in two papers. Sternberg (1970) coprecipitated ovalbumin, hemoglobin, pepsin, and amyloglucosidase from protein crudes using four heteropoly anions. Sternberg removed the inorganic anions by dialysis, ultrafiltration, and ion exchange, recovering fair to good activities in some cases. Astrup et al. (1954) worked with six heteropolyanions in staged purification of serum proteins including α- and γ-globulins.

Tannic acids are polyphenolic compounds (sometimes conjugated with one or more saccharides) from plant extracts. They are quite diverse in structure, depending on the plant source. Sigma sells a crude tannic acid that is convenient to start with. An advantage to using tannates as precipitants is that they function in

RCU IVSTITVT LIBRARY

neutral pH regions, pH ~4 to 8. Hence, severe acid and hydrolytic conditions, often necessary with the metallic heteropolyanions, may be avoided with tannates, which are all-organic anions. Little detail is known concerning how tannate precipitation works. Tannates are sometimes effective in precipitating proteins on a broad front, and inclusively, but in some systems fail to precipitate proteins to which they are bound (Hagerman and Butler, 1991). Amounts of tannic acid and of tannate needed for precipitation of diverse proteins range from approximately half as much by weight as the sought-for protein, down to quite smaller amounts of tannin; these quantities are also quite dependent on pH. Hagerman and Butler (1978, 1991) survey principal parameters for controlling precipitation of individual proteins such as albumin and lysozyme. They recommend quebracho tannin and commercial tannic acids as initial agents for attempting precipitation of mixtures of proteins. Although there are gaps in the precipitating power of tannate compounds for proteins, they provide alternatives for scaleable, reversible procedures under conditions where the metallic heteropolyanions (strong acid) are too severe. The strong spectrophotometric absorption spectra of tannins when reacted with Folin phenol reagent or with ferric chloride, both of which generate characteristic colors for phenols, afford convenient means for quantitating tannates in coprecipitates and in soluble remnants (Hagerman and Butler, 1978).

Hydrophobic ion-pairing entanglement ions

It may seem surprising that ligands such as those used in Basic Protocol 8—especially detergents—are efficient precipitating agents; these reagents are normally used in solubilizing and denaturing proteins. Detergent anions (i.e., dodecyl sulfate) acting as protein coprecipitants were first studied at length by Putnam and Neurath (1944) for seven proteins. Since then, the detergent/protein and subsequent complex/complex association reactions have sometimes been called hydrophobic ion-pairing reactions. A rather strict detergent-anion to protein-cation association occurs in 1:1 stoichiometry to form ion pairs between charged groups; simultaneously an alkane/alkane association occurs between the hydrophobic tails. The two sets of forces strongly pull the complexes together and out of the solution to agglomerate and form the visible coprecipitate. Protein-molecule to protein-molecule association may also occur, but there are rather few detailed studies of this. The ion/ion association, which is the electrostatic component of HIP, is dependent on and adjusted by the pH, because the pH and the number of protein H^+–titratable side chains determine the number of net cationic charges on the global protein molecule—i.e., Z_{H^+}. This, in turn, determines the number of ligand anions expected to bind when coprecipitates are formed. Because strong anions from detergents usually bind strongly, there is seldom a need to add extra ligand (detergent) to provide for large amounts of free (unbound) ligand. Between 60% and 95% of the total detergent anions added under the aforementioned conditions are likely to be bound for 10-carbon, 12-carbon, and larger detergent sulfates. However, short-chain detergent anions—e.g., hexyl and octyl sulfates—are usually poor HIP precipitants.

Matrix-stacking ligand coprecipitation

In organic anion–matrix ligands, the rigid azoaromatic sulfonates are able to stack their tail groups to force association and coprecipitation. These reagents have several similarities to flexible detergent coprecipitating anions (HIP agents; see discussion above). As in the case of the flexible detergents, matrix-ligand coprecipitation is sharply dependent on protein electrostatic charge, thence on pH, on protein side-chain composition, and on the isoionic point. In contrast to the detergent anions, whose coprecipitating powers are mainly dependent on alkane-chain length, matrix-stacking ligands are dependent on organic structural detail and placement of groups, not simply on size. The placement of short alkane "reinforcement" substituents and the location of sulfonate anions on aromatic rings, as well as the location of tautomerizing hydroxyl groups, make stacking-ligand structural character more complicated and unpredictable than that of flexible-detergent ligands. In practice, one may need to experiment with a variety of matrix ligands to find an optimal kind for selectively coprecipitating each protein.

It appears that matrix-stacking ligands need their hydrophobic tail groups to extend some distance away (greater than ~10 to 15 Å) from the sulfonated head group (Matulis and Lovrien, 1996). This requirement presumably maximizes tail-tail stacking and hydrophobic association, distancing them so as not to interfere with sulfonate group–protein cation association. In any case, functions of matrix ligands are sensitive to placement of substituents such as alkane groups on the azoaromatic rings, as

POLYTECHNIC UNIVERSITY LIBRARY

well as the number of such substituents. In practice, one expects to initially experiment with ~3 to 5 such ligands to find a ligand suitable for investigation in more detail. Because matrix ligands generally are quite protective of proteins with which they coprecipitate, it may not be necessary to always develop the coprecipitation stage of protein isolation at cold temperatures. Indeed, the method often interfaces well with a heat-shock step to clear out unwanted proteins susceptible to heat shocking. Pilot experiments therefore can generally be carried out at ordinary room temperatures.

Matrix ligands strongly coprecipitate proteins. However, overall isolation processes for most proteins usually need an exit. The protein and ligand should be released from one another by resin-exchange trapping as described in Basic Protocol 2. Hence, it may occur that somewhat more weakly coprecipitating, but more easily released ligands may be optimal in the procedures, so as to allow proteins to dissolve, ready for assay or the next isolation steps.

Di- and trivalent metal cation precipitation

Metal cations exert themselves in three ways to precipitate proteins. First, their charges add to protein molecule net charge, enhancing binding of coprecipitating ligand ions such as matrix or detergent sulfate anions. Second, metal ions draw in protein side chains and lysine amines, as well as carboxylate and histidyl side chains, to fill metal ion orbitals with their electron pairs. Protein molecules thus act as large chelating agents in a manner analogous to the behavior of EDTA and other multidentate chelators and become tightened and sometimes protected because of the chelation to M^{2+}. Finally, M^{2+} and M^{3+} ions can become complexed with buffer ions and other electrolytes chosen by the researcher. When that happens, actual net charge and remaining metal ion ligand positions available to the protein may be adjusted to modulate protein precipitation. Metal ion complexes of M^{2+} and M^{3+} may actually be made neutral, or even anionic, depending on presence of chloride, acetate, or citrate, and their concentrations (in the 10^{-3} to 10^{-1} M range); this phenomenon is also dependent on pH. Cotton and Wilkinson (1988) cite $Zn(H_2O)_6^{+2}$, $ZnCl(H_2O)_5^{+1}$, $ZnCl_2(H_2O)_4$, $ZnCl_4^{-2}$, and $ZnCl_4(H_2O)_4^{-2}$ as examples. Cobalt and a number of other transition metal cations complex with ammonia and water molecules to make a series of coordinate cations of considerably larger size than the parent Co^{2+} but which still carry the central metal ion's charge. On the other hand, addition of CN^- or SCN^- generates a series of complexes such as $Fe(CN)_6^{-3}$ which are strong, very stable anions. A number of metal cations—e.g., Ni^{+2} and Zn^{+2}—are capable of switching configuration from square planar to tetrahedral to octahedral, depending on coordinate ligands, chelating agent, and solvent conditions. Some metal cations useful in protein precipitation are amphoteric, switching water molecules and OH^- ligands into and out of metal orbital positions depending on pH. Metal cations such as Al^{3+} strongly bind oxo-ligands, including water molecules and hydroxyl (OH^-) to form metallic gels that settle or centrifuge down and capture proteins by adsorption (Collingwood et al., 1988). This mode of precipitation is often called flocculation. Flocculated products tend to have uncertain composition, but have the advantage of being dense and separable by low-speed centrifugation or simply by settling.

If the choice of metal ion is otherwise not obvious, the first choice as protein coprecipitant is the zinc ion. Zn^{2+} is of intermediate strength in chelation-coordination reactions with respect to the kinds of ligands offered by amine, carboxylate, and imidazole side chains. Therefore it can be "reversed"—i.e., removed from coprecipitates. Zn^{2+} rather rapidly exchanges ligands that coordinate with it (Berg and Shi, 1996). More importantly, zinc ions do not promote electron transfer and oxidation-reduction reactions, whereas many of the transition metals—e.g., iron, copper, and nickel ions—indeed do so. Hence Zn^{2+} is fairly safe to use for precipitating proteins with sensitive sulfhydryl (–SH) groups. Other metal ions–e.g., Cu^{2+} and Ni^{2+} promote oxidation, usually irreversibly, and therefore can be rather destructive. Zn^{2+} in the form, for example, of zinc chloride, is also the probable first choice to use as an "assist" agent in conjunction with other precipitants. Atha and Ingham (1981) show excellent examples of the ability of $ZnCl_2$ to decisively decrease the concentration of PEG crowding agent necessary to precipitate out human serum albumin from a 0.5% solution. Zn^{2+} appears to tighten the albumin molecule's conformation, easing PEG's task in precipitating the protein.

CHAPTER 5
Production of Recombinant Proteins

INTRODUCTION

This chapter deals with the production of recombinant proteins using the expression systems in common use. Methods describing the actual construction of the expression vectors or plasmids containing the genes coding the proteins of interest are described in detail elsewhere (Sambrook et al., 1989; Ausubel et al., 1997).

The most widely used and most important expression systems are those using *E. coli* as the host cell. An overview of the production of proteins in *E. coli* is provided in *UNIT 5.1*. General strategies for gene expression described include direct intracellular expression, secretion of the protein into the periplasmic space, and the expression of fusion proteins. Some of these strategies (e.g., secretion procedures) are used to overcome the common problem of inclusion body formation (see *UNIT 6.1* for additional discussion); others (e.g., fusions involving affinity tags) are used simply to assist in protein purification. Many of the expression vectors discussed are commercially available and suppliers are indicated throughout the text.

Protocols describing protein expression in transformed *E. coli* cells are provided in *UNITS 5.2 & 5.3*. First, protein expression in *E. coli* requires that a suitable host strain (tabulated in *UNIT 5.2*) be transformed with an expression vector. Electroporation, a quick and simple method for transforming *E. coli* host strains, is presented in *UNIT 5.2*. Second, the growth conditions and methods used to induce gene expression are optimized for the particular host strain and controllable transcriptional promoter used. Standard procedures for small-scale expression in shaker flasks using several of the most common expression vectors are also presented, along with protocols for determining plasmid stability and storing transformed strains at low temperature. Finally, methods for establishing the level of protein expression as well as solubility and location (intracellular or periplasmic) are described.

Once suitable host/vector combinations have been selected on the basis of the small-scale experiments described in *UNIT 5.2*, large-scale protein production can be carried out in fermentors with careful monitoring of cell growth. *UNIT 5.3* describes fermentation in batch mode using a fixed amount of medium. For higher-density fermentations, the fed-batch process is described: in this procedure the growth carbon source is continuously fed into the culture. Modifications to the standard fed-batch process are used to introduce the heavy atom derivative selenomethionine into recombinant proteins to facilitate X-ray structure determination and to uniformly label proteins with combinations of the stable isotopes ^{2}H, ^{13}C, and ^{15}N. Isotopically labeled proteins are required for high-resolution structural studies using nuclear magnetic resonance (NMR) spectroscopy (see *UNIT 7.1* for additional details). Protocols for growth monitoring and sterility checking are also included.

There are several eukaryotic cell–based expression systems available for overproducing recombinant proteins (consult Ausubel et al., 1997, Chapter 16), and most of these will eventually be covered in this chapter. One system, which uses insect cells infected with recombinant baculovirus, has become widely used. An overview of protein expression using the baculovirus system is given in *UNIT 5.4*. References covering the molecular

BOSTON UNIVERSITY LIBRARY

biology required to construct the recombinant baculovirus vector that expresses the gene of interest are provided in the overview. Furthermore, references to protocols describing small-scale expression experiments are supplied in the introduction to *UNIT 5.5*.

The large-scale growth of insect cells infected with baculovirus is carried out in bioreactors, requiring large (liter) amounts of viral stock (*UNIT 5.5*). These stocks must have known titers and are analyzed in small-scale (1- to 3-liter) cultures in order to evaluate and optimize protein expression. For developing protein purification methods and for isolating moderate amounts of recombinant protein, small-scale cultures in shaker or spinner culture flasks may provide adequate starting material. Large-scale insect cell culture is carried out with more sophisticated equipment using bioreactors in either batch mode or perfusion mode. Cell harvesting is carried out by centrifugation or tangential-flow microfiltration. The cells (for intracellular expressed proteins) or the culture medium (for secreted proteins) are retained for downstream processing. Other protocols in this unit provide methods for preparing samples for SDS-PAGE to check protein expression levels and for monitoring nutrient levels in culture media.

Yeast is another important eukaryotic host used for protein expression. The molecular biology of *Saccharomyces cerevisiae* (baker's yeast) is described in Chapter 13 of Ausubel et al. (1997). An overview of protein expression in *S. cerevisiae* is given in *UNIT 5.6*, which details, as a case study, some of the machinations required to achieve high-level production of the human glycoprotein antithrombin 111 secreted into the extracellular medium.

Other strains of yeast apart from *S. cerevisiae* have also been used for heterologous protein expression, including the methylotropic yeast *Pichia pastoris*. There may be some advantages to using this host system over the more common *S. cerevisiae*, as expression levels, especially for intracellular proteins, can be higher. Protein expression using the *P. pastoris* system is reviewed in *UNIT 5.7*. The commonly used expression vectors are described, together with many examples of proteins successfully expressed with the system. Protocols describing the culture of the *S. cerevisiae* and *P. pastoris* strains with various expression vectors for heterologous protein expression are provided in *UNIT 5.8*.

An overview of protein expression using mammalian cells is presented in *UNIT 5.9*. The unit reviews the stages involved in protein production using the stable expression approach. As post-transcriptional modification and intracellular protein transportation are integral components of mammalian protein expression, descriptions of these mechanisms are included. Protocols for the production of recombinant proteins in mammalian cells using various culture configurations are described in *UNIT 5.10*. These are supplemented with a number of support protocols that include the first steps in downstream processing.

The choice of protein expression system does depend on the intended use and characteristics of the protein. If a protein can be expressed in *E. coli* in a soluble state either directly into the cytoplasm or by secretion into the periplasm, then it may be possible to isolate large amounts of correctly folded and active protein (e.g., see *UNIT 6.2*). On the other hand, if the protein must be post-translationally modified (i.e., glycosylated or phosphorylated), a eukaryotic expression system must be used. Furthermore, if the protein is expressed in an insoluble state in *E. coli*, one way to circumvent this problem is to try expression in an eukaryotic system.

The baculovirus system complements *E. coli* expression systems and for many investigators is the system of choice, especially for expressing post-translationally modified proteins. Yeast has the advantage that it is cheap to grow (analogous to *E. coli*) but can produce hyperglycosylated proteins; moreover, occasionally protein produced at high levels is insoluble (again analogous to *E. coli*). If a glycoprotein is required for clinical

BCU IASI CENTRAL UNIVERSITY LIBRARY

studies, it must usually be produced by mammalian cell expression, as discussed in detail in *UNITS 5.9 & 5.10*. However, no expression system is without its drawbacks; some of the problems reported using the baculovirus and yeast systems are mentioned in *UNITS 5.4 & 5.6-5.8* and elsewhere (Bradley, 1990). In addition, a brief summary of the advantages and disadvantages of all the commonly used host systems is given in the booklet *The Recombinant Protein Handbook* (Pharmacia Biotech, 1994).

Production of Recombinant Proteins in *Escherichia coli*

The genetics and biochemistry of *Escherichia coli* are probably the best understood of any known organism. The knowledge gained in the study of *E. coli* biology has been applied to the development of many of today's molecular cloning techniques. Most cloning vectors and methods utilize *E. coli* or its phages as a preferred host, primarily because of the ease with which the bacterium can be grown and genetically manipulated. These same characteristics made *E. coli* an attractive early choice as a host for the production of large quantities of protein encoded by cloned genes. Aside from its well-studied biology, *E. coli* is suitable as the basis of an expression system because of its rapid doubling time and its ability to grow in inexpensive media. Years of study devoted to gene expression in *E. coli* have provided numerous choices for transcriptional and translational control elements that can be applied to the expression of foreign genes (*UNITS 5.2 & 5.3*). As a result, *E. coli* has been and continues to be the expression system of choice and a substantial body of literature has accumulated on the successful expression of foreign genes in this host. Several problems with protein expression in *E. coli* have been encountered, and many have been ultimately solved. This unit describes methods that have been developed for production of recombinant proteins in *E. coli* and potential pitfalls that may be encountered.

GENERAL STRATEGIES FOR GENE EXPRESSION IN *E. COLI*

The basic approach used to express foreign genes in *E. coli* begins with insertion of the gene into an expression vector, usually a plasmid (obtained from a commercial supplier or from the author of a published study). The next step involves transforming a suitable *E. coli* host strain with the plasmid, for example, by electroporation (*UNIT 5.2*). Transformed cells are then subjected to evaluation of plasmid stability and foreign protein expression following induction of the controllable transcriptional promoter present in the expression vector (*UNIT 5.2*). Once small-scale shaker flask experiments have identified successful expression systems (*UNIT 5.2*), the transformed *E. coli* strain can be used in large-scale fermentation systems (*UNIT 5.3*), which can be designed to produce recombinant proteins with altered amino acids (e.g., selenomethionine in place of methionine) or stable isotope tags to facilitate structural studies. Production is followed by protein purification (Chapter 6) and characterization (Chapter 7).

If the gene to be expressed in *E. coli* is of eukaryotic origin, it must be a cDNA copy, as *E. coli* will not recognize and splice out introns from transcripts of genomic copies of eukaryotic genes. Typical *E. coli* expression vectors contain the following elements.

Selectable Marker

Expression plasmids contain sequences encoding a selectable marker to ensure maintenance of the vector in the host cell. Commonly used selectable markers in *E. coli* include *bla* (which encodes β-lactamase and confers resistance to ampicillin and other β-lactam antibiotics), *cat* (which encodes chloramphenicol acetyltransferase and confers resistance to chloramphenicol), and *tet* (which encodes a membrane protein that confers resistance to tetracycline).

Origin of Replication

Replication of a plasmid as an independent extrachromosomal element is controlled by its origin of replication. Some plasmids are under so-called stringent control, wherein the plasmid's replication is coupled to replication of the host chromosome. As such, only one or at most a few copies of the plasmid are maintained in each cell. More commonly, *E. coli* vectors used for expression of cloned genes utilize relaxed control such as the ColE1 replicon found in pBR322 and derivatives. These plasmids generally have copy numbers of 10 to 200 plasmids per cell. The presence of multiple copies of the gene and its associated control elements can provide advantages in mRNA production and, as a result, may be reflected in an increase in the total amount of protein that accumulates. Nevertheless, the reduced copy number of stringent replicons may sometimes be advantageous: it allows for modulation of gene dosage, which can sometimes be helpful for altering the kinetics of expression or reducing the basal transcriptional levels of the plasmid-encoded promoter.

Promoters

An essential component of expression vectors is a controllable transcriptional promoter which, when induced, can direct the production of large amounts of mRNA from the cloned gene. There are a variety of controllable promoters that are routinely used. The *lac* promoter system utilizes the transcriptional control elements from the *E. coli* β-galactosidase gene (Miller and Reznikoff, 1978). The *lac* promoter (like the tac and trc promoters, which have optimized *lac* promoter RNA polymerase recognition sequences) is controlled by binding of *lac* repressor (the *lacI* gene product) to an operator sequence in the promoter region. The repressor can be expressed either from the host genome (single copy, in which case an overexpressing repressor allele called *lacI*^{q} should be used) or from the expression vector (multiple copies, with resultant tighter transcriptional control). Induction of the promoter is generally accomplished by the addition of isopropyl-β-D-thiogalactopyranoside (IPTG), a lactose analog that binds to the *lac* repressor and prohibits its binding to the *lac* operator. An example of a commercially available *lac* promoter vector is pBluescript (Stratagene). The pKK223-3 vector from Pharmacia Biotech is a source of the tac promoter. The trc promoter is used in the vectors pSE280, pSE380, and pSE420 from Invitrogen.

Another commonly used promoter system utilizes the major leftward promoter of bacteriophage lambda, p_L, and its control elements (Shimatake and Rosenberg, 1981). The p_L promoter contained on an expression vector can be controlled by the phage-encoded *c*I repressor, which is typically expressed from an integrated copy of the phage in the host genome. A temperature-sensitive *c*I repressor (called *c*I857) is usually used; this encodes a repressor that is functional at lower temperatures but denatures at temperatures above 37.5°C. Thus, p_L-mediated protein synthesis can be induced by a simple temperature shift. Alternatively, temperature-independent p_L promoter systems have been developed that utilize a *c*I repressor gene under the control of a separate inducible promoter (Mieschendahl et al., 1986; LaVallie et al., 1993a). A commercial source for the p_L vector is the pP$_L$-Lambda vector from Pharmacia Biotech.

The T7 RNA polymerase promoter is another popular transcriptional control element for heterologous expression. The RNA polymerase from bacteriophage T7 is highly selective for specific T7 phage promoter sequences that are uncommon in other DNAs (Studier et al., 1990). A gene of interest placed under the control of a T7 promoter can be selectively expressed by induction of host-encoded T7 polymerase synthesis, which itself is under the control of an inducible promoter such as *lac*. Induction of T7 polymerase synthesis causes almost exclusive expression of the gene under the control of the T7 promoter. In some instances, the T7 transcription can outcompete the host RNA polymerase, resulting in accumulation of large amounts of the gene product of interest. There are many commercially available expression vectors that utilize the T7 polymerase/promoter system, such as the pGEMEX vectors from Promega, the pRSET vectors from Invitrogen, and the pET vectors from Novagen.

Translation Initiation Sequence

Initiation of translation on mRNAs requires the presence of a so-called Shine and Dalgarno sequence or ribosome binding site (RBS) in close proximity to an initiator methionine (Shine and Dalgarno, 1974). The RBS consists of a purine-rich stretch of nucleotides complementary to the 3′ end of 16S RNA, located 5 to 13 bases 5′ to an initiator ATG. RBS elements typically used in expression vectors derive from well-translated *E. coli* or bacteriophage genes. For instance, the pTrcHis and pRSET vectors (Invitrogen) and the pGEMEX (Promega) vectors use the T7 gene 10 RBS.

SPECIFIC EXPRESSION STRATEGIES

Direct Intracellular Expression

Direct expression refers to the fusing of the coding sequence of interest to transcriptional and translational control sequences on an expression vector, with an initiator methionine codon preceding the open reading frame. This approach can be used to produce cytoplasmic proteins, and it can also be used for the intracellular expression of normally secreted proteins. In the latter case, the DNA sequence encoding the signal peptide is replaced by the initiator methionine codon.

Success with the direct approach is often variable. First, translation initiation is inconsistent due to the fact that sequences 3′ to the initiator methionine can influence the efficiency of ribosome binding (Looman et al., 1987; Bucheler et al., 1990). For reasons that are not fully understood, maximizing the A+T content of the 5′ end of the coding sequence (taking advantage of the degeneracy of the

genetic code) can sometimes improve the efficiency of translation initiation (De Lamarter et al., 1985; Devlin et al., 1988). Second, recombinant proteins produced in the cytoplasm often form dense, insoluble aggregates of protein called *inclusion bodies* (Schein, 1989). In some ways, this can be viewed as an advantage because inclusion bodies are easily purified from the soluble proteins (*UNIT 6.3*). In addition, proteins in inclusion bodies are usually resistant to proteolytic degradation. In cases where activity of the expressed protein is unnecessary (e.g., in production of protein to be used as an antigen to produce antibodies), inclusion body formation and resultant insolubility of the protein may actually be preferred. If active protein is desired, however, recovery of properly folded protein from inclusion bodies requires the total denaturation of the protein using reagents such as urea or guanidine, followed by subsequent refolding using protocols that must be determined empirically for each protein (*UNIT 6.5*). The success of refolding protocols is variable, depending on the particular protein, and may yield little or no correctly folded material.

If protein insolubility is encountered and is undesired, production of soluble protein can sometimes be enhanced by simply lowering the growth temperature during protein synthesis (Bishai et al., 1987; Schein and Noteborn, 1988). If the protein is normally secreted, then a secretory construct may produce more soluble protein (see section on Secretion). Alternatively, production of the protein as a fusion to a highly soluble partner may alleviate the problem (see section on Fusion Proteins).

If the gene is expressed poorly, translation efficiency may be a problem. If this is the case, it is often advantageous to maximize the A+T content of the 5′ coding sequence and/or replace the RBS with a sequence that initiates translation more efficiently (Olins and Rangwala, 1989). Another potential cause of poor translation is a preponderance of "rare" codons in the coding sequence, that is, codons that are underutilized by *E. coli* (Robinson et al., 1984). Stretches of contiguous rare codons may contribute to lower expression levels and should be changed to codons that are frequently used by *E. coli*. Finally, poor expression levels may be caused by product instability. In this instance, use of host strains and induction methods that minimize proteolytic degradation should be attempted (*UNIT 5.2*).

In instances where the gene is expressed well and soluble protein can be produced, the protein must then be purified from an abundant and diverse mixture of other *E. coli* cytoplasmic proteins. This can be a difficult and time-consuming process, and the purification scheme will be different for each protein based on its physical and biochemical characteristics (Chapters 6 and 8).

Secretion

Secretion of proteins in *E. coli* is mediated by the presence of an N-terminal signal sequence that is cleaved after translocation of the protein. Expression of cloned gene products as secreted proteins in *E. coli* has been utilized as an alternative to cytoplasmic expression for proteins that are normally secreted. In *E. coli* the protein is secreted to the periplasmic space between the cytoplasmic and outer membranes, in contrast to extracellular secretion that occurs in gram-positive bacteria and eukaryotic cells. The result is that in *E. coli* the secreted protein remains cell-associated, although in a "compartment" separated from the cytoplasmic proteins that make up the vast majority of the total cellular protein. This can be advantageous in terms of protein purification if techniques are used that release only periplasmic contents while leaving the cytoplasmic membrane intact (Neu and Heppel, 1965).

Secretion of heterologous gene products has been successfully employed for various proteins that are difficult to produce in the cytoplasm of *E. coli* as soluble and active proteins, including various growth factors (Cheah et al., 1994), receptors (Fuh et al., 1990), and recombinant Fab fragments (Skerra, 1994). Although eukaryotic signal peptides have been reported to function in *E. coli*, most secretion vectors utilize signal peptides derived from prokaryotic genes such as the *ompA* (Takahara et al., 1988; Cheah et al., 1994), *pelB* (Power et al., 1992), *phoA* (Oka et al., 1985), or *hisJ* (Vasquez et al., 1989) signal peptides. Although secretion provides an alternative to cytoplasmic expression that can sometimes result in the production of properly folded and active protein, the yield of desired protein is often low. Also, overexpressed gene products have been reported to form inclusion bodies even in the periplasm (Bowden and Georgiou, 1990); so secretion is not a panacea for the problem of insolubility.

Fusion Proteins

The problems that have plagued successful overexpression of cloned gene products in *E. coli*—namely, inconsistent expression levels,

BRUNEL UNIVERSITY LIBRARY

protein insolubility, and difficult purification of the gene product from *E. coli* contaminants—have been most successfully addressed by the use of fusion proteins. Fusion proteins are created via a translational fusion of the coding sequence for the protein of interest to a gene for a highly expressed protein partner (or "carrier" protein). Typically, the gene encoding the protein of interest is inserted in-frame 3′ to the coding sequence for the carrier protein, in place of the usual termination codon. This allows uniform translational initiation of the carrier protein regardless of the coding sequence fused to its 3′ end, which helps to ensure consistent expression levels.

Carrier proteins are usually chosen based on specific attributes that make them suitable in this role. The most successful fusion systems employ the maltose-binding protein (MBP; Maina et al., 1988), glutathione *S*-transferase (GST; Smith and Johnson, 1988), or thioredoxin (TRX; LaVallie et al., 1993a). The genes for these proteins are well expressed, and the proteins are highly soluble and provide specific physical characteristics or affinities to aid purification. These qualities also extend to the protein sequences fused to them, thereby enhancing the solubility and ease of purification of the entire fusion protein.

Maltose-binding protein is a 43-kDa secreted protein from *E. coli*. As its name implies, it binds specifically to maltose or amylose, a property that can be exploited in purification schemes (Guan et al., 1988). MBP fusions can be secreted into the periplasm, or they can be expressed without the MBP signal peptide, which results in accumulation of the fusion protein in the cytoplasm. MBP fusions are usually well expressed, and a high proportion of MBP fusion proteins are soluble. MBP expression plasmids and reagents can be purchased from New England Biolabs. The MBP expression vectors utilize the tac promoter and a plasmid-encoded *lacI*^{q} gene for transcriptional control. These vectors contain a recognition sequence for the site-specific protease factor Xa to allow removal of the carrier protein following purification (see section on Fusion Protein Cleavage Methods).

Glutathione *S*-transferase is a 26-kDa cytoplasmic protein from *Schistosoma japonicum*. Carboxy-terminal protein fusions to GST are usually soluble and well-expressed (Smith and Johnson, 1988). GST binds specifically to glutathione, and GST fusion proteins can be purified in a single step from crude bacterial lysates by affinity chromatography on immobilized glutathione. The GST expression plasmids are available from Pharmacia Biotech, and utilize the tac promoter and plasmid-encoded *lacI*^{q} for inducible transcriptional control. A variety of vectors are available which contain either the factor Xa or the thrombin recognition sequence to allow cleavage and removal of the GST from the protein of interest following affinity purification (see section on Fusion Protein Cleavage Methods).

Thioredoxin is a 12-kDa intracellular *E. coli* protein. It is very soluble, can be highly overexpressed from plasmid vectors (Lunn et al., 1984), and has been shown to be a very successful fusion partner. A wide variety of gene products can be produced abundantly in soluble fashion when fused to TRX (LaVallie et al., 1993a). Two different characteristics of TRX can be exploited to allow specific purification of some TRX fusion proteins. TRX accumulates at specific sites along the inner surface of the cytoplasmic membrane, called Bayer's patches or adhesion zones. These sites constitute an osmotically sensitive compartment, and TRX (and some TRX fusions) can be selectively released from the cytoplasm and separated from the bulk of *E. coli* proteins by osmotic shock or freeze/thaw procedures. In addition, TRX is thermostable, and some TRX fusions can be purified by selective thermal denaturation of contaminants. In instances where osmotic shock or heat treatments do not provide adequate purification, an altered TRX protein has been developed (E.R.L., manuscript in preparation) that allows specific purification by metal-chelate affinity chromatography. The TRX fusion vector (available from Invitrogen) contains an enterokinase recognition sequence positioned at the junction between TRX and the C-terminal fusion partner.

In addition to the carrier proteins listed above, there are many other proteins that have been used to produce fusions for the purpose of generating large amounts of protein in *E. coli*. Among them are *E. coli* β-galactosidase (Ruther and Muller-Hill, 1983) and TrpE (Yansura, 1990), *Staphylococcus aureus* protein A (Nilsson et al., 1985; vector available from Pharmacia Biotech), chloramphenicol acetyltransferase (Knott et al., 1988), bacteriophage lambda cII protein (Nagai and Thøgersen, 1987), and various carbohydrate-binding proteins (Taylor and Drickamer, 1991; Helman and Mantsala, 1992). Table 5.1.1 lists many fusion partners that have been described in the literature.

ECU IASTATE UNIVERSITY LIBRARY

Table 5.1.1 Common Fusion Proteins

Fusion protein	Specific purification method[a]
Maltose-binding protein	Amylose binding
Glutathione *S*-transferase	Glutathione binding
Thioredoxin	Selective release, heat stability, MCAC
Protein A	IgG binding
β-Galactosidase	APTG or anti-β-galactosidase antibody binding
Chloramphenicol acetyltransferase	Chloramphenicol binding
lac repressor	*lac* operator binding (Lundeberg et al., 1990)
Galactose-binding protein	Galactose binding
Cyclomaltodextrin glucanotransferase	Cyclodextrin binding
Lambda *c*II protein	None
TrpE protein	None

[a]MCAC, metal-chelate affinity chromatography; IgG, immunoglobulin G; APTG, *p*-amino-β-D-thiogalactoside.

Table 5.1.2 Fusion Tags

Amino acid tag	Ligand	Reference/supplier
Polyhistidine	Metal-chelate affinity resin	Qiagen
Polyaspartic acid	Anion-exchange resin	Dalbøge et al. (1987)
Polyarginine	Cation-exchange resin	Brewer and Sassenfeld (1985)
Polyphenylalanine	HIC resin[a]	Persson et al. (1988)
Polycysteine	Thiol	Persson et al. (1988)
In vivo biotinylated peptide	Avidin or streptavidin	Schatz (1993)
Flag peptide	Anti-Flag antibody	International Biotechnologies (IBI)

[a]HIC, hydrophobic interaction chromatography (*UNIT 8.4*).

Fusion Tags

Fusion tags are small stretches of amino acids added to the N-terminal or C-terminal end of a protein. Although they do not usually help to increase expression levels or protein solubility, they can be advantageous in protein purification and detection. The tags are generally chosen either because they encode an epitope that can be detected and purified using an antibody that binds to it, or because the tag amino acids provide a physical characteristic that can be exploited for easy and specific purification. A popular example is the polyhistidine tag, usually a stretch of six consecutive histidine residues added to either the N or C terminus of a protein, that provides specific binding to metal chelate resins. There are a number of polyhistidine vectors on the market, such as the pTrcHis vector from Invitrogen. Other examples, such as polyarginine (Brewer and Sassenfeld, 1985) or polyaspartic acid tags (Dalbøge et al., 1987), can be used to alter the binding behavior of a protein on ion-exchange resins. A noteworthy fusion tag is a small stretch of amino acids recognized and biotinylated in vivo by the biotin-protein ligase in *E. coli* (Schatz, 1993). This allows specific capture of the biotinylated protein on immobilized avidin or streptavidin. Table 5.1.2 lists a number of the more popular fusion tags.

Fusion Protein Cleavage Methods

Whereas fusion proteins and fusion tags have proved useful for the reasons outlined above, the end result is that the protein of interest will carry additional sequences that may hamper its functional activity. There are several methods for removal of the carrier protein, which can be divided into chemical cleavage methods and enzymatic (proteolytic) cleavage methods. Chemical cleavage of fusion proteins can be accomplished with reagents such as cyanogen bromide (Met↓; Itakura et al., 1977; Villa et al., 1989), 2-(2-

BOSTON CENTRAL UNIVERSITY LIBRARY

nitrophenylsulfenyl)-3-methyl-3′-bromoindolinine or BNPS-skatole (Trp↓; Dykes et al., 1988), hydroxylamine (Asn↓Gly; Bornstein and Balian, 1977), or low pH (Asp↓Pro; Szoka et al., 1986). The use of these reagents, as described in *UNIT 11.4*, can be applied to the site-specific cleavage of fusion proteins provided that the fusion is designed so that the chemically labile bond is positioned at the desired point of scission. Chemical cleavage reagents tend to be inexpensive and efficient, and many of the reactions can be performed under denaturing conditions so that even insoluble proteins can be cleaved. However, one disadvantage of using chemical cleavage reagents for the site-specific cleavage of fusion proteins is that the reactions are generally performed under extremes of pH and/or temperature that can result in unwanted amino acid side-chain modifications. Chemical cleavage methods also have the disadvantage of low specificity, so it is more likely that the protein of interest will contain an internal cleavage site.

Enzymatic digestion is usually the method of choice for soluble fusion protein cleavage as the reactions are carried out under relatively mild conditions. Proteases such as trypsin (Lys↓ or Arg↓), endoproteinase Asp-N (↓Asp), and Staph V8 *S. aureus* V8 protease (Glu↓ or Asp↓) can be used in this role. High-quality trypsin, *S. aureus* V8 protease (endoproteinase Glu-C), and endoproteinase Asp-N can all be obtained from Boehringer Mannheim. These proteases, like chemical cleaving reagents, are limited by their low degree of specificity (recognizing and cleaving at single amino acids).

Alternatively, thrombin (Leu-Val-Pro-Arg↓Gly-Ser; Gearing et al., 1989), factor Xa [Ile-Glu(or Asp)-Gly-Arg↓; Nagai and Thøgersen, 1984, 1987; Gardella et al., 1990], renin (Pro-Phe-His-Leu↓Leu-Val-Tyr; Haffey et al., 1987), collagenase (Pro-X↓Gly-Pro-Y↓; Germino and Bastia, 1984), and enterokinase (Asp-Asp-Asp-Asp-Lys↓; Dykes et al., 1988; LaVallie et al., 1993b) are much more suitable in this role. All of these enzymes have extended substrate recognition sequences (up to seven amino acids in the case of renin), which greatly reduces the likelihood of unwanted cleavages elsewhere in the protein. Factor Xa and enterokinase are most useful for cleaving off C-terminal fusion partners because they cleave on the carboxyl-terminal side of their respective recognition sequences. This allows the release of fusion partners containing their authentic amino terminus. In addition, the catalytic subunit of bovine enterokinase has been cloned and expressed (LaVallie et al., 1993b), and the recombinant enzyme has been shown to be approximately 100-fold more efficient than the native intestinally derived enzyme in fusion protein cleavage reactions (Racie et al., 1995). The recombinant enterokinase is available from New England Biolabs.

SUMMARY

Methods for the overexpression of cloned gene products in *E. coli* have improved significantly since it was first attempted. Common problems such as variable expression levels, inclusion body formation, and purification difficulties have been successfully addressed by advancements in expression technology. Probably the most significant of these advancements has been the development of fusion proteins and fusion tag expression and purification techniques. These methods have resulted in more consistent production of soluble and active protein, and have allowed for simple and efficient purification of the proteins from bacterial lysates. Although the production of soluble, properly folded, and active recombinant proteins in *E. coli* is still not guaranteed, the likelihood of success is far greater than it was just a few years ago. This progress should help ensure that *E. coli* will continue to be the host organism of choice for recombinant protein production.

Selection of *Escherichia coli* Expression Systems

Use of *Escherichia coli* as a protein factory capable of being retooled to meet the needs of the investigator is a well-established alternative to purification of proteins from natural sources. Moreover, expression—the directed synthesis of a foreign gene—is often the next step for researchers who have isolated a gene and want to study the protein it encodes.

Table 5.2.1 lists the most useful expression strains for fermentation processes. A more comprehensive table of *E. coli* strains can be found in Raleigh et al. (1989) and Sambrook et al. (1989). A summary of four of the most widely used expression systems is presented in Table 5.2.2. The available expression systems have been reviewed (e.g., Goeddel, 1990). A number of systems use thermoinducible promoters that predictably induce the *E. coli* heat-shock response. We therefore frequently use strains partially or totally defective in this response (e.g., Coli B, HB101, or DH5α) since some of the induced heat-shock proteins are proteases.

Table 5.2.1 *Escherichia coli* Fermentation Strains

[a]The *trp* promoter is naturally induced by tryptophan starvation; addition of IAA is optional.

This unit describes standard procedures for several expression systems, namely, temperature induction via the p_L promoter (Basic Protocol 1) and chemical induction via the *trp* promoter (Basic Protocol 2), *lac* or tac promoters (Alternate Protocol 1), and the T7 promoter (Alternate Protocol 2). These protocols require that the gene encoding the protein of interest has been identified and cloned into an appropriate expression vector using standard molecular biology techniques. Transformation of a suitable host strain (e.g., by electroporation; Support Protocol 2) is also a prerequisite.

Once an appropriate expression strain has been selected, the stability of the plasmid can be analyzed (Support Protocol 2) and the strain can be stored (Support Protocol 3). Other support protocols in this unit describe how to prepare samples for electrophoresis (Support Protocol 4), how to analyze the solubility of the expressed proteins (Support Protocol 5), and how to make samples of periplasmic extracts (Support Protocol 6) and extracellular media (using TCA precipitation, Support Protocol 7). Many of the support protocols are small-scale analysis procedures that are used to guide subsequent purification strategies and determine the suitability of the expression system for further development and scale-up.

BASIC PROTOCOL 1

EXPRESSION UNDER CONTROL OF p_L PROMOTER: TEMPERATURE INDUCTION

Protein expression from vectors containing the p_L promoter from bacteriophage lambda can be induced by raising the temperature. The *E. coli* host strains used with such vectors must harbor a temperature-sensitive repressor protein encoded by *cI857* either integrated in the host chromosome as a dormant phage, or built into the same plasmid as the one carrying the heterologous gene. At high temperatures, expression of the *cI857* gene is inactive, releasing the repression and allowing transcription of genes downstream of the p_L promoter. In this protocol, cells are first grown at 30°C to the desired density in rich medium containing antibiotic to maintain the plasmid; synthesis of the protein is then induced by a temperature shift to 42°C. The proper antibiotic is determined by the expression vector.

Materials

Host *E. coli* strain (e.g., Coli B, W3110) transformed with plasmid containing gene for the protein of interest under control of p_L promoter (see Support Protocol 1)
LB medium (see recipe)
Antibiotic stock solution (see recipe)

20-ml sterile culture tube
42°C shaking water bath
150-ml shaker flask, sterile

BGU IASI CENTRAL UNIVERSITY LIBRARY

1. Prepare a small liquid culture in stationary phase of the host *E. coli* strain transformed with plasmid containing the gene for the protein of interest under control of the p_L promoter by inoculating a 20-ml tube containing 2 ml LB medium (supplemented with appropriate antibiotic stock solution) with a single colony from a fresh agar plate of the same medium. Incubate the tube overnight on a rotary shaker at 30°C, 200 rpm. Do not allow the temperature to exceed 30°C.

   Temperatures above 30°C may induce expression of the target protein and interfere with growth.

2. The next morning, read the OD_{600} against water as a blank to verify that cultures have reached stationary phase.

   In a 1-cm light path cuvette, the OD should be in the range of 1 to 2. (An OD of 1 is equal to 0.5-1 × 10^9 cells/ml.) The OD is read on an aliquot of the culture diluted 10-fold in PBS buffer against water as a blank. Readings higher than 0.4 are not correlated to cell density. Absolute absorbance values will vary among spectrophotometers depending on the cuvettes, light path, and construction of the apparatus.

3. Place a 150-ml shaker flask containing 50 ml LB medium with antibiotic in a 42°C shaking water bath to prewarm the medium.

   Again, make sure that the temperature is accurate; too low a temperature will lead to incomplete repressor inactivation and poor induction. To measure temperature, insert a thermometer into a control flask (containing water only) also placed in the water bath.

4. Transfer the 2-ml overnight culture into the flask containing prewarmed medium. Take a 1-ml sample and process it as described in step 5. Return the 50-ml culture to the 42°C shaking water bath and incubate 3 hr with vigorous agitation (200 rpm). At the end of the incubation, take another 1-ml sample.

   Inoculation and sample removal should be done quickly to keep the temperature stable.

5. Microcentrifuge each sample 2 min at maximum speed, room temperature. Discard the supernatant and prepare for analysis by SDS-PAGE (see Support Protocol 4).

   Pellets may be stored at –20°C at this point before SDS-PAGE. They may be stored frozen indefinitely (for years).

6. Use the remainder of the 50-ml culture to analyze plasmid stability (Support Protocol 2), determine solubility of the sample (see Support Protocol 5), and prepare periplasmic extracts or extracellular medium samples (see Support Protocol 5 and Support Protocol 6) to obtain recombinant protein. Store leftover culture, if desired (see Support Protocol 3).

EXPRESSION UNDER CONTROL OF *trp* PROMOTER: CHEMICAL INDUCTION

BASIC PROTOCOL 2

This protocol describes induction of synthesis of the protein of interest under control of the *E. coli trp* promoter. Cells are grown to exponential phase in minimal medium to achieve tryptophan starvation, and residual *trp* repressor is inactivated by the tryptophan analog indole-3-acrylic acid. Incubation of cultures is conducted at 37°C throughout, and the choice of antibiotic is determined by the plasmid construction.

Materials

Host *E. coli* strain transformed with plasmid containing *trp* promoter and gene for the protein of interest (see Support Protocol 1)
M9 medium (see recipe) with 0.5% (w/v) Casamino Acids (Difco)
Antibiotic stock solution (see recipe)

BOU MASTER CENTRAL UNIVERSITY LIBRARY

Indole-3-acrylic acid (IAA; see recipe)

20-ml sterile culture tube
150-ml shaker flask
37°C orbital shaker

1. Use a single colony of the host *E. coli* strain transformed with plasmid containing *trp* promoter and gene for the protein of interest, from a fresh agar plate, to inoculate a 20-ml tube containing 2 ml of M9 medium with 0.5% Casamino Acids and appropriate antibiotic. Incubate the tube overnight at 37°C on a rotary shaker (200 rpm).
2. The next morning, read OD_{600} against water as a blank.
3. Transfer the overnight culture to a 150-ml shaker flask containing 50 ml of M9/Casamino Acids supplemented with appropriate antibiotic.
4. Take an initial 1-ml sample as a control for uninduced cells and either immediately treat as described in step 7 or refrigerate at –20°C until ready to perform step 7.
5. Incubate the culture for 1 to 2 hr in a 37°C orbital shaker with vigorous agitation (200 rpm). Check OD_{600}.

   The cells should be in full exponential growth phase (OD_{600} of 0.2 to 0.5).
6. Induce protein expression by adding IAA (2.5 ml of the 400× stock per liter) to a final concentration of 25 µg/ml. Incubate for another 3 hr and take a second (final) 1-ml sample.
7. For each 1-ml sample, microcentrifuge 2 min at maximum speed, room temperature. Discard supernatant and prepare the sample for SDS-PAGE analysis (see Support Protocol 4).

   If it is not convenient to electrophorese samples right away, pellets can be stored at –20°C.
8. Use remaining culture for analysis of protein solubility (see Support Protocol 5), and localization of proteins in the periplasmic space (see Support Protocol 6) or culture medium (see Support Protocol 7), or analysis of plasmid stability (if needed; see Support Protocol 2). If desired, store leftover cells (see Support Protocol 3).

ALTERNATE PROTOCOL 1

EXPRESSION UNDER CONTROL OF *lac*/tac PROMOTERS

For protein expression under control of the *lac* promoter or tac promoter (a hybrid between *lac* and *trp* promoters), induction via release of the *lac* repressor is achieved by adding isopropyl-β-thiogalactopyranoside (IPTG) to cultures, which binds and inactivates the repressor. The host strain must harbor the *lacI* repressor gene in the chromosome or in a plasmid (either the same plasmid as the target gene or a compatible one).

***Additional Materials** (also see Basic Protocol 2)*

Host *E. coli* strain containing *lacI* repressor gene and transformed with plasmid containing *lac* or tac promoter and gene for the protein of interest
Isopropyl-β-thiogalactopyranoside (IPTG; see recipe)

For this protocol, follow steps 1 to 5 of Basic Protocol 2 (*trp* promoter), substituting the appropriate host strain as the starting material. Replace step 6 with the following and then return to steps 7 and 8 of Basic Protocol 2.

6a. Induce protein expression by adding IPTG to a final concentration of 0.4 to 1.0 mM. Incubate for a further 3 hr and take a second (final) 1-ml sample.

BSU IASRI / CENTRAL UNIVERSITY LIBRARY

T7 RNA POLYMERASE/PROMOTER EXPRESSION SYSTEM

ALTERNATE PROTOCOL 2

The T7 RNA polymerase/promoter expression system utilized in this protocol involves induction, via the *lacUV5* promoter, of the highly active and efficient T7 RNA polymerase, which binds to the T7 promoter (p_{T7}) and transcribes genes under its control. An appropriate *E. coli* strain—in which the T7 polymerase gene under control of *lacUV5* has been integrated into host DNA and which has been transformed with plasmid DNA containing an ampicillin-resistance gene and the gene for the protein of interest under control of p_{T7}—is induced with IPTG. In a variation of the system, T7 lysozyme, which binds the polymerase and thus eliminates transcription under noninduced conditions, can be introduced on a second plasmid (e.g., pLysE or pLysS, which also encode chloramphenicol resistance) and maintained under selection with a second antibiotic.

Additional Materials (also see Basic Protocol 2)

Host *E. coli* strain transformed with DNA encoding T7 RNA polymerase under control of *lacUV5* promoter, plasmid containing p_{T7} and gene for the protein of interest, and (optional) plasmid containing gene for T7 lysozyme
Isopropyl-β-thiogalactopyranoside (IPTG; see recipe)

For this protocol, follow steps 1 to 5 of Basic Protocol 2, except begin with the appropriate transformed *E. coli* host strain, use ampicillin selection, and include a second antibiotic if the optional T7 lysozyme plasmid strategy is used (e.g., chloramphenicol at 30 mg/liter for pLysE or pLysL transformation). Replace step 6 with the following and return to steps 7 and 8 of Basic Protocol 2.

6b. Induce protein expression by adding IPTG to the culture to achieve a final concentration of 0.5 to 1.0 mM (10 to 20 ml of 100× stock per liter). Incubate for another 3 hr before taking a second (final) 1-ml sample.

TRANSFORMATION BY ELECTROPORATION

SUPPORT PROTOCOL 1

Electroporation is a quick, simple, and efficient method for introducing foreign DNA into *E. coli* (i.e., transformation). Cultures of the appropriate host strain are grown to exponential phase in rich medium to produce competent cells (i.e., cells able to take up foreign DNA). Competent cells can be stored frozen at –80°C until use. Plasmid DNA is introduced by subjecting cells to an electrical pulse, using a commercially available electroporation apparatus, and cells are allowed to recover in rich medium supplemented with glucose. After the transformation, strains can be stored (see Support Protocol 3) and/or used for protein expression (see Basic Protocol 1, Basic Protocol 2, Alternate Protocol 1, and Alternate Protocol 2). Plasmid stability analysis (see Support Protocol 2) is not absolutely required and should be carried out only in cases where expression with a given strain is not reproducible. Several different host strains can be transformed in the same experiment to allow investigation of the influence of the host on protein expression efficiency.

Materials

Host *E. coli* strain
LB medium (see recipe)
Water, ice-cold
10% (w/v) glycerol, ice-cold
Plasmid DNA
SOC medium (see recipe)
LB plates with appropriate antibiotic (see recipe)

BHARATHIAR UNIVERSITY LIBRARY

1-liter and 50-ml centrifuge bottles, chilled
Centrifuge (e.g., Sorvall RC3B equipped with H6000A rotor, or equivalent), 4°C
1.5-ml sterile microcentrifuge tubes, chilled
Electroporation apparatus (e.g., *E. coli* Pulser Apparatus; Bio-Rad)
Electroporation cuvettes, 0.2-cm electrode gap, sterile and prechilled

Prepare the competent cells

1. Prepare an overnight culture with the *E. coli* host strain to be transformed by inoculating a 100-ml flask containing 20 ml LB medium with a single colony from an LB agar plate. As the host strain is plasmid free, do not add any antibiotic; with shaking, grow at 37°C. The next morning, verify that cultures have reached stationary growth phase (OD_{600} of 1 to 2).

   In the case of T7 expression and when using the additional pLys plasmids (optional; see Alternate Protocol 2), the host already contains a plasmid and should be kept under selective pressure (30 mg/liter chloramphenicol).

2. Transfer the overnight culture to 800 ml LB medium in a 3-liter Erlenmeyer flask. Incubate cells 1 to 2 hr in a 37°C orbital shaker with vigorous agitation (200 rpm).

3. Verify that the cells are in full exponential growth phase (OD_{600} of 0.5 to 0.6). Transfer cells to a 1-liter chilled centrifuge bottle.

4. Centrifuge 15 min at 4000 × *g*, 4°C. Discard supernatant and resuspend the pellet in 5 to 10 ml ice-cold water. Bring to a final volume of 800 ml with ice-cold water.

5. Repeat step 4 twice.

6a. *If cells are to be transformed the same day:* Resuspend the pellet in ice-cold water to a final volume of 50 ml, and pellet again in a chilled 50-ml centrifuge bottle. Discard supernatant, estimate the volume of the pellet, and add an equal volume of ice-cold water. Vortex, distribute 100-µl aliquots into prechilled 1.5-ml sterile microcentrifuge tubes, and keep on ice. Proceed to step 7.

6b. *If competent cells are to be stored frozen:* Resuspend the pellet in ice-cold 10% glycerol to a final volume of 50 ml, and pellet again in a 50-ml centrifuge bottle. Discard supernatant, estimate the volume of the pellet, and add an equal volume of ice-cold 10% glycerol. Vortex, place 100-µl aliquots into prechilled 1.5-ml microcentrifuge tubes, and store in a −80°C freezer.

   To use frozen competent cells for transformation, thaw microcentrifuge tubes on ice and proceed to step 7.

Transform the competent cells

7. Add 5 pg to 0.5 µg plasmid DNA (in 1 to 5 µl) to 100 µl competent cells. Mix by inverting the tube several times by hand. Keep on ice.

   Quantities of plasmid DNA can be estimated from average yields of a plasmid prep, or measured by UV absorbance.

   Some host cells (such as E. coli B) require more DNA for efficient transformation, depending on their ability to restrict foreign DNA.

8. Set the electroporation apparatus to 2.5 kV, 25 µF, 200 Ω.

   Some variation of the resistance (100 to 400 Ω) may be necessary to obtain optimal results (see Seidman et al., 1989).

9. Transfer the DNA and cells to a prechilled electroporation cuvette, wipe away ice and

BSU IASI CENTRAL UNIVERSITY LIBRARY

water from the cuvette outer walls, place the cuvette into the electroporation chamber, and apply the electrical pulse.

Include a control with no DNA to ensure that transformants arise only by introduction of foreign DNA into the competent cells.

10. Remove the cuvette, immediately add 1 ml SOC medium and transfer the contents of the cuvette to a 20-ml sterile culture tube. Incubate 60 min with moderate shaking.

    The incubation temperature depends on the expression vector. Use 30°C for p_L-based expression plasmids and 37°C for others.

11. Spread aliquots of the transformation culture (10 to 100 µl) on LB plates with appropriate antibiotic. Check for appearance of individual colonies after 24 to 48 hr of incubation.

12. Individually streak and label 5 to 10 colonies from transformation plates onto fresh plates with appropriate antibiotic to ensure they are pure, viable, and antibiotic resistant.

13. Store an aliquot of each strain (see Support Protocol 3). Proceed to the appropriate expression protocol (see Basic Protocol 1, Basic Protocol 2, Alternate Protocol 1, and Alternate Protocol 2).

PLASMID STABILITY ANALYSIS

SUPPORT PROTOCOL 2

Analysis of plasmid stability is important for assessing the quality of recombinant strains. This check is not absolutely required and is really only needed in cases where expression with a given strain is not reproducible. An aliquot of the frozen stock is thawed and serial dilutions of the strain are prepared and spread on plates containing rich medium with or without the antibiotic used to maintain the plasmid. Plated cultures are grown overnight, colonies counted, and the percentage of plasmid-carrying cells in the population determined.

Materials

PBS (*APPENDIX 2E*)
Transformed *E. coli* host strain (Basic Protocols 1 and 2, Alternate Protocols 1 and 2)
LB plates with and without antibiotic (see recipe)
20-ml sterile culture tubes
Sterile triangular glass rod

NOTE: Cells should be kept in an ice bath throughout the procedure to minimize alterations to the samples.

1. Set up a rack of 20-ml sterile culture tubes and place 9 ml PBS in each tube. Pipet a 1-ml sample of the transformed *E. coli* host strain to be analyzed into the first tube. Vortex for 5 sec.

   An OD_{600} reading should be done before diluting the culture to facilitate steps 2-3.

2. With a new sterile pipet, transfer 1 ml from the previous tube into the next tube containing PBS.

3. Repeat step 2 until the final desired dilution is reached.

   The dilution range depends on the initial density of the culture. For an OD_{600} of 1, the final dilution factor should be 10^{-6}.

BCU LAS / CENTRAL UNIVERSITY LIBRARY

4. Spread 100 µl of the final three dilutions onto triplicate sets of LB plates with and without antibiotic. Use a sterile triangular glass rod to achieve an even distribution of the cells on the plate.

   Start with the highest dilution (i.e., with the fewest cells) to minimize effects of carryover from one plate to the next. As 0.1 ml is spread on the plate and as a culture at an OD_{600} of 1 contains ~10^9 cells/ml, diluting the culture to a maximum of 10^{-6} should give ~100 colonies per plate.

5. Incubate plates overnight at the appropriate temperature.

   A temperature of 30°C should be used for p_L-based expression strains and 37°C for all others. Incubate the plates upside down to collect water condensation in the plate cover.

6. The next morning, count the colonies on each plate. Calculate the number of cells present in the original sample that grew on LB and the number that grew on LB plus antibiotic. Determine the ratio of the two numbers to obtain the percentage of plasmid-carrying cells in the population.

   Serial dilutions can be made by a different combination of volumes leading eventually to a different dilution factor (0.1 ml into tubes containing 0.9 ml, 0.01 ml in 0.99 ml, etc.) For best accuracy, count plates with >30 colonies.

   Strains showing more than 50% plasmid retention before induction of protein expression are acceptable.

SUPPORT PROTOCOL 3

STRAIN STORAGE

For long-term storage, recombinant *E. coli* strains are kept at low temperature, frozen with a cryopreservative agent. A temperature of –80°C is sufficient for most strains. Multiple strains can be prepared in parallel and frozen in a single operation. It is good practice to keep at least one frozen copy that is not thawed and frozen repeatedly. The frozen stocks can be retrieved from storage and used for protein expression (Basic Protocols 1 and 2, and Alternate Protocols 1 and 2).

Materials

Transformed *E. coli* host strain (see Support Protocol 1)
LB medium (see recipe)
Antibiotic stock solution (see recipe)
20% (w/v) glycerol, dispersed in sterile cryovials (see recipe)
LB plate (see recipe)

20-ml culture tube
30° or 37°C orbital shaker

1. Grow an overnight culture of transformed *E. coli* host strain by inoculating 2 ml of LB medium (supplemented with appropriate antibiotic, if necessary) in a 20-ml culture tube with a single colony from a fresh agar plate. Incubate the tube overnight on an orbital shaker. The next morning, verify that cells are in stationary phase (OD_{600} of 1 to 2).

   The incubation temperature is dependent on the expression vector. Use 30°C for p_L-based systems and 37°C for others.

2. Inoculate a 20-ml tube (containing 2 ml LB plus appropriate antibiotic) with 50 µl from the overnight culture. Incubate for 2 to 3 hr.

ESU IASI / CENTRAL UNIVERSITY LIBRARY

3. Add 0.9 ml culture to each cryovial, label, vortex well, and freeze immediately. Store frozen strains at –80°C.
4. To start a new culture from the frozen stock, scrape the surface of the vial with a sterile loop and either streak on an LB plate or dip into liquid medium. Return the cryovial to –80°C for storage.

Several hundred strains can be stored in a single freezer, but it is advisable to have alarm and safety devices against mechanical or electrical failure.

PREPARATION OF SAMPLES FOR ANALYSIS BY SDS-PAGE

SUPPORT PROTOCOL 4

Electrophoretic separation of proteins in a cell extract (total lysate or fraction of the cell) by SDS-PAGE is described in detail in *UNIT 10.1*. This protocol describes only the preparation of the samples and applies to material derived from Basic Protocol 1, Basic Protocol 2, Alternate Protocol 1, and Alternate Protocol 2. The objective is to bring all proteins of the sample into solution in a denatured state so the mixture can be resolved by one-dimensional electrophoresis in SDS gels. Solubilization is achieved by sonicating samples in a buffer containing detergent and reducing agents, followed by brief heating. A large excess of sample is prepared so that it can be reloaded on several gels, if necessary. Once solubilized in SDS sample buffer, samples can be stored for years at –20°C.

Materials

Sample of interest
2× and 1× SDS sample buffer (*UNIT 10.1*)

Toothpicks, sterile
Sonicator (Branson, with microtip)

1a. *For soluble samples (e.g., soluble cellular proteins, periplasmic extracts, extracellular medium):* Add the sample of interest to an equal volume of 2× SDS sample buffer in a 1.5-ml microcentrifuge tube and proceed directly to step 4.

1b. *For pellet samples (total cells, insoluble fraction, trichloroacetic acid precipitate):* Transfer 5 to 10 mg pellet material from the sample of interest with a sterile toothpick to a preweighed 1.5-ml microcentrifuge tube.

2. Add 1× SDS sample buffer, using 400 µl per 10 mg pellet.
3. Sonicate 10 sec with a sonicator (with power setting at 30 to 50 W) to resuspend the pellet.

Be careful to avoid foaming by keeping the sonicator probe well below the liquid surface at all times.

4. Heat to 90°C for 5 min in a heating block.

After cooling, samples are ready to be applied to gel wells for electrophoresis (UNIT 10.1). Loading amounts are based on gel and well dimensions, as well as the detection system to be used (e.g., silver staining is 100 times more sensitive than Coomassie blue staining; UNIT 10.5). Recommended amounts are as follows: 0.5 to 1 µl for microgels (e.g., 4.3 × 5 cm; 0.45 mm thick), 5 to 10 µl for minigels (e.g., 7.3 × 8.3 cm; 1 mm thick), and up to 20 µl for full-size gels (e.g., 14 × 14 cm; 1.5 mm thick).

CHIMIE

BCU IAŞI / CENTRAL UNIVERSITY LIBRARY

SUPPORT PROTOCOL 5

SOLUBILITY ANALYSIS

Analysis of the solubility of recombinant proteins is needed to determine the subsequent purification strategy (*UNIT 6.1*). The protocol is based on mechanical disruption of cells followed by high-speed centrifugation to separate the soluble fraction from the insoluble fraction. Samples are then prepared for SDS-PAGE analysis (see Support Protocol 4).

Materials

Transformed *E. coli* host cells expressing the protein of interest
25 mM HEPES (pH 7.6; autoclave and store up to 1 yr at 4°C)
50- and 5-ml centrifuge tubes
Centrifuge (e.g., Sorvall RC5B equipped with SS34 rotor), 4°C
Sonicator

NOTE: Cells should be kept in an ice bath throughout the procedure to minimize alterations to the samples.

1. Harvest 25 ml transformed *E. coli* host cells expressing the protein of interest by centrifuging 15 min at 4000 × *g*, 4°C, in a 50-ml centrifuge tube.
2. Discard the supernatant and resuspend the pellet in 1 to 1.5 ml 25 mM HEPES (pH 7.6) to obtain an OD_{600} of ~40.
3. Set the tube in an ice bath and sonicate three times for 1 min each, allowing 30-sec intervals between pulses.
4. Place a 100-µl aliquot of the cell lysate (total protein) in a 1.5-ml microcentrifuge tube and keep at –20°C for later analysis (step 7).

   The 30-sec intervals allow the suspension to cool down between sonications. Be careful to avoid overheating at all stages.

5. Transfer the suspension to a 5-ml centrifuge tube and centrifuge 30 min at 30,000 × *g* (16,000 rpm in an SS-34 rotor), 4°C.
6. Pour off supernatant (soluble fraction) into another 5-ml tube to separate it from the pellet (insoluble fraction).
7. Prepare the three fractions (total, soluble, and insoluble proteins) for analysis by SDS-PAGE (see Support Protocol 4).

   The proportion of soluble/insoluble proteins can be quantified after SDS-PAGE separation (UNIT 10.1), staining of gels (UNIT 10.5), and scanning densitometry of the gels.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

PREPARATION OF PERIPLASMIC EXTRACTS

This protocol describes a small-scale procedure to confirm the expression of proteins that are designed to be localized to the periplasmic space of *E. coli*. It is based on subjecting cells to an osmotic shock in a concentrated sucrose solution, which mechanically forces the contents of the periplasm through the outer membrane and cell wall.

Materials

Transformed *E. coli* cells expressing the protein of interest
PBS (*APPENDIX 2E*)
20% (w/v) sucrose/10 mM Tris·Cl (pH 7.5), ice-cold
0.5 M EDTA (pH 8.0)
Ice-cold water

Microcentrifuge, 4°C

NOTE: Cells should be kept in an ice bath throughout the procedure to minimize alterations to the samples.

Release the periplasmic proteins by osmotic shock

1. Place 1 ml transformed *E. coli* cells expressing the protein of interest in a 1.5-ml microcentrifuge tube and microcentrifuge 2 min at maximum speed, 4°C.

   Depending on the culture density, adjust the volume of the sample so that it contains ~2 × 10^9 cells. (An OD_{600} of 1 is equivalent to 10^9 cells/ml).

2. Discard supernatant and resuspend the pellet in 1 ml PBS. Vortex tube well.

3. Pellet the cells again in the microcentrifuge for 2 min.

4. Discard supernatant and resuspend the pellet in 150 µl cold 20% sucrose/10 mM Tris·Cl (pH 7.5). Vortex well and add 5 µl of 0.5 M EDTA (pH 8.0).

5. Save a 50-µl aliquot representing the whole-cell fraction and store at –20°C. Leave remainder of the sample on ice for 10 min.

   The short incubation allows time for the EDTA to loosen the cell wall structure.

Separate the sample into periplasmic and cytoplasmic/membrane fractions

6. Pellet the cells for 5 min in the microcentrifuge.

7. Discard supernatant and resuspend the pellet by vigorous vortexing in 100 µl ice-cold water.

8. Leave on ice for 10 min and then repeat step 6.

9. Carefully collect and save the supernatant, which contains the periplasmic fraction in a 1.5-ml microcentrifuge tube and store at –20°C.

10. Eliminate remaining fluid from the pellet with a cotton-tipped swab and resuspend the sample in 100 µl ice-cold water. Save this solution as the cytoplasmic and membrane fraction.

11. Prepare the three fractions (whole-cell, periplasm, and cytoplasm/membrane fractions) for SDS-PAGE analysis (see Support Protocol 4).

BCU Main Central University Library

PREPARATION OF EXTRACELLULAR MEDIUM SAMPLES

Expression systems that direct extracellular secretion of the desired protein can be checked by analyzing samples of the culture medium. This protocol describes treatment of culture media with trichloroacetic acid (TCA) to precipitate extracellular proteins and thus concentrate proteins for subsequent analysis. Addition of bovine serum albumin (BSA) may be helpful if protein concentrations in the medium are low.

Materials

Transformed *E. coli* cells expressing the protein of interest
2 g/liter BSA (optional; sterilize through a 0.22-µm filter and store ≤1 month at 4°C)
200 g/liter trichloroacetic acid (TCA; sterilize through a 0.22-µm filter and store ≤1 month at 4°C)
70% (v/v) ethanol
0.22-µm filters suitable for aqueous solutions
Microcentrifuge, 4°C
Ice bath

1. Place a 1-ml culture of *E. coli* cells expressing the protein of interest in a 1.5-ml microcentrifuge tube and microcentrifuge 2 min at maximum speed, 4°C.
2. Collect the supernatant and pass it through a 0.22-µm filter into a 1.5-ml microcentrifuge tube. Discard pellet.
3. Add 100 µl of 2 g/liter BSA, if necessary.

   BSA acts as a carrier and nucleus for precipitation. It can be omitted if the medium already contains >100 mg/l of protein.
4. Add 1 ml of 200 g/liter TCA, vortex well, and leave the tube on ice for 15 to 30 min to allow proteins to precipitate.
5. Microcentrifuge for 10 min at maximum speed, 4°C.
6. Discard supernatant and wash the pellet at least twice with 2 ml of 70% ethanol.

   The washings remove the TCA, which would otherwise disturb subsequent analysis by SDS-PAGE.
7. Prepare the pellet for analysis by SDS-PAGE (see Support Protocol 4).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Antibiotic stock solutions (1000× concentrated)

Ampicillin: Prepare a 40 g/liter stock in water. Store ≤2 weeks at 4°C.

Chloramphenicol: Prepare a 30 g/liter stock in ethanol. Store ≤1 year at –20°C.

Kanamycin: Prepare a 40 g/liter stock in water. Store ≤1 year at 4°C.

Tetracycline: Prepare a 5 g/liter stock in 70% ethanol. Store ≤1 year in the dark at –20°C.

Sterilize all stock solutions by filtration through a 0.22-µm filter before use. Aliquot in 5 to 10 portions, depending on quantities needed.

BSU IASRI CENTRAL UNIVERSITY LIBRARY

Glycerol

Dispense 1 ml of 20% (v/v) glycerol into 2.5-ml cryovials. Autoclave with the caps loose. After sterilization, tighten the caps. Store up to 1 year at 4°C.

An entire rack of cryovials can be prepared at once, as they can be stored for a long time.

Indole-3-acrylic acid (IAA)

Store IAA as a powder at 4°C. Prepare solution fresh as a 400× concentrated solution in ethanol (10 g/liter).

Isopropyl-β-thiogalactopyranoside (IPTG)

Store IPTG as a powder at −20°C. Prepare solution fresh as a 100× concentrated solution in water (50 mM, i.e., 11.9 mg/liter). Sterilize by filtration before use.

LB medium

Per liter:
10 g Bacto-tryptone
5 g yeast extract
5 g NaCl
10 ml 1 N NaOH (to pH 7.0)
H_2O to 1 liter
Sterilize 30 min at 121°C

Dispense into 20-ml culture tubes (2 or 5 ml/tube) or shaker flasks (see Commentary). Plug opening with rigid aluminum cap or with hydrophobic cotton wool covered with aluminum foil.

Antibiotics should be added (if appropriate) just before use.

The original recipe for LB medium (sometimes referred to Luria or Lenox broth) does not contain NaOH. There are many different recipes for LB that differ only in the amount of NaOH added. We use this formula in our own work. Even though the pH is adjusted to near 7.0 with NaOH, the medium is not highly buffered, and the pH of a culture growing in it drops as it nears saturation.

M9 minimal medium

Per liter:
6 g Na_2HPO_4
3 g KH_2PO_4
1 g NH_4Cl
0.5 g NaCl
3 mg $CaCl_2$
H_2O to 1 liter
Sterilize 30 min at 121°C

Dispense into 20-ml culture tubes (2 or 5 ml/tube) or shaker flasks (see Commentary). Plug opening with rigid aluminium cap or with hydrophobic cotton wool covered with aluminum foil.

Antibiotics should be added (if appropriate) just before use.

BCU IAS / CENTRAL UNIVERSITY LIBRARY

SOC medium

Per liter:

5 g yeast extract
20 g Bacto-tryptone
580 mg NaCl (10 mM)
186 mg KCl (2.5 mM)
940 mg $MgCl_2$ (10 mM)
1.2 g $MgSO_4$ (10 mM)
3.6 g glucose (20 mM)
H_2O to 1 liter
Sterilize 30 min at 121°C

Dispense into 20-ml culture tubes (2 or 5 ml/tube) or shaker flasks (see Commentary). Plug opening with rigid aluminium cap or with hydrophobic cotton wool covered with aluminum foil.

Antibiotics should be added (if appropriate) just before use.

The amounts given in the recipe refer to the anhydrous salts.

Plates

Use liquid medium formulation (see recipes for LB, SOC, and M9 media) and add 20 g/liter agar.

For LB or SOC plates, autoclave the agar together with the other ingredients. For M9 plates, autoclave 20 g agar in 800 ml water for 15 min, then add sterile concentrated M9 medium (i.e., make up components in 200 rather than 1000 ml water). Cool the agar solutions to about 50°C before adding desired supplements (i.e., antibiotics; see recipe). The media will stay liquid at 50°C but will rapidly solidify if the temperature drops below 45°C. Pour 32 to 40 ml medium into each sterile disposable petri dish to get 25 to 30 plates per liter. Allow the agar to solidify. Dry the plates by leaving them out at room temperature for 2 or 3 days, or by leaving them with the lids off for 30 min in a 37°C incubator or in a laminar-flow hood. Store dry plates at 4°C, wrapped in the original bags used to package the empty plates. Antibiotic-containing plates have a limited shelf-life: 2 weeks for ampicillin; 6 weeks for chloramphenicol, kanamycin, and tetracycline.

COMMENTARY

Background Information

As described in *UNIT 5.1*, the choice of an expression system and corresponding host strain for the production of a recombinant protein in *E. coli* is dictated by the ultimate goal of the study. If the protein is needed for structural studies requiring tens to hundreds of milligrams of a given protein, correctly folded, then either secretion of the protein or high-level production inside the cell (followed by protein refolding if the protein is in aggregated form; *UNIT 6.5*) may be the methods of choice. If an antigen is needed for raising antibodies, gene fusion strategies are often the method of choice. The toxicity of some recombinant proteins will also drive a requirement for very tightly repressed systems such as T7 RNA polymerase, which have particular host requirements (see Alternate Protocol 2). In other words, the type of protein and its solubility dictate the vector construction and, thus, the *E. coli* host strain used.

The p_L promoter from lambda phage initiates high levels of transcription that can be repressed by the cI protein (Shatzman et al., 1990). A temperature-sensitive mutant of the repressor, cI857, which is inactive at high temperature, allows induction by a temperature shift from 30° to 42°C (Remaut et al., 1981). The repressor gene can be carried on the host chromosome or on the same plasmid as p_L. In general, induction of p_L is most efficient when the cells are in full exponential growth phase in a rich medium (see Basic Protocol 1).

Tac is a hybrid between *lac* and *trp* promoters and is regulated by the same *lacI* repressor as *lac*. These promoters are inducible by the addition of a nonmetabolizable galactose analog, isopropyl-β-thiogalactopyranoside

ECU IASI - CENTRAL UNIVERSITY LIBRARY

(IPTG), which binds and inactivates the repressor. The *lacI* repressor gene can be integrated in the host chromosome, on the same plasmid as the target gene, or on another compatible one. This expression system (see Alternate Protocol 1) is extensively used for recombinant protein expression (Harris, 1983).

T7-driven expression (see Alternate Protocol 2) is based on the efficiency and specificity of the phage T7 RNA polymerase for initiating transcription from T7 promoters (Tabor, 1990; Studier and Moffat, 1986). Two elements are introduced into the host cell: the T7 polymerase gene, under control of an inducible promoter (*lacUV5*), which is integrated into the host DNA as a λDE3 lysogen; and the target gene, which is introduced on a plasmid under control of the T7 promoter. This plasmid also carries an antibiotic (ampicillin or kanamycin) resistance gene for selection. Two hosts are routinely used: *E. coli* BL21 and HMS174 (Table 5.2.1). For toxic target gene products and because basal levels of the T7 polymerase can promote some transcription of the target gene, a third optional element—T7 lysozyme—is sometimes added. T7 lysozyme binds the T7 polymerase, thereby inactivating it and eliminating transcription of the target gene under noninduced conditions. The T7 lysozyme gene is carried by either of two plasmids (pLysE or pLysS) and expressed constitutively. Both plasmids also carry a selection marker (chloramphenicol-resistance gene). The pET system is a series of vectors for cloning into the T7 promoter system (Novagen). Some vectors carry an ampicillin-resistance gene; others carry kanamycin resistance. Novagen distributes a complete set of tools associated with the system, including host strains, competent cells, and pLysS and pLysE vectors.

The promoter for the tryptophan operon (*trp*) is strong and well-repressed under basal conditions (Somerville, 1988). Tryptophan present in the culture medium acts as a corepressor by binding to the *trp* repressor. This complex binds to the operator and prevents transcription. As the cells consume tryptophan for growth, its concentration decreases to a point where the operator is unbound and transcription of genes downstream (see Basic Protocol 2) is initiated. Addition of indole-3-acrylic acid (IAA), a tryptophan structural analog, inactivates any residual repressor.

High-copy-number plasmids are desirable for high-level expression but also often result in plasmid loss. An analysis of plasmid stability (see Support Protocol 2) allows evaluation of plasmid loss and control of the quality and integrity of recombinant strains.

The relative proportions of soluble and insoluble recombinant protein (also referred to as inclusion bodies) are affected by many variables such as protein primary sequence, expression system, and host strain. Environmental factors such as temperature and pH of the culture are also key determinants as there is a consensus that lower temperatures (20° to 25°C) lead to a higher proportion of soluble protein. The soluble/insoluble ratio dictates the subsequent purification strategy (see Chapter 6). It is therefore essential to analyze the recombinant protein solubility (see Support Protocol 5), which, in some cases, can be considered more important than the total protein expression level. Secretion to the periplasmic space should be evaluated, because this compartment provides a more oxidative environment than the cytoplasm and favors disulfide bridge formation.

With an appropriate expression system, it is possible to direct secretion of the recombinant protein to the periplasmic space of *E. coli* (Hsiung et al., 1986). Analysis of expression and confirmation of the proper localization thus require the preparation of a periplasmic extract. The osmotic shock method (see Support Protocol 6) to prepare periplasmic extracts was originally described by Koshland (1980). Fusion to periplasmic (e.g., MalE, PhoA) or outer membrane (e.g., OmpA, LamB) protein signal peptides has been extensively used to direct recombinant proteins to the periplasm (Hsuing et al., 1986; Hewinson and Russell, 1993; Karim et al., 1993). This approach was successfully applied to antibody fragments (Carter et al., 1992; Plückthun, 1991). Complete secretion to the extracellular medium has also been achieved by fusing the gene of interest at the N terminus to protein A signal peptide from *S. aureus* or at the C terminal domain of hemolysin A (reviewed in Blight and Holland, 1994).

Several expression systems are now available that allow efficient secretion of the recombinant protein into the extracellular medium (Blight and Holland, 1994). However, the secreted protein is usually quite dilute and concentration of the protein is necessary for analyzing and confirming expression by SDS-PAGE. Ultrafiltration or precipitation can be used for this purpose. This protocol describes precipitation by TCA, which is quick, reliable, and inexpensive. Several samples can be handled in the same batch.

PUBLISHED BY THE CENTRAL LIBRARY

Critical Parameters and Troubleshooting

The temperature shift necessary to induce p_L will also induce a heat-shock response, and in particular turn on some protease genes. Also, some host strains (such as *E. coli* HB101) do not tolerate 42°C, and growth is drastically reduced at this temperature. Tac and *lac* are weaker than p_L or *trp*, but still drive high-level expression of some proteins. They are not recommended for toxic gene products because repression is often incomplete. This occurs because, in the *lac* operon, normal repression is mediated in part by an operator site internal to the *lacZ* gene, which is not usually found in the target gene. It is also important to note that repression is more efficient with the mutated repressor gene $lacI^Q$.

The expression protocols can be scaled to any size shaker flask, as long as the culture is kept well aerated (maximum ratio of liquid/flask volume of 0.3). Care should also be taken to ensure that incubation temperatures are accurate. It takes ~95 min for an 800-ml culture in a 2-liter flask to heat from 20° to 42°C in an air shaker at 200 rpm. Pre-warming of culture media can be done adequately in an air shaker if enough time is allowed for the warmup, but it is probably better if a water bath is used for temperature induction steps.

Attempts to increase solubility of proteins formed in aggregates or inclusion bodies have included coexpression with chaperones, manipulation of temperature and other environmental factors, and secretion of the desired protein to the periplasmic space and/or the extracellular medium. These strategies have been reviewed (Hockney, 1994).

Incomplete repression is quite frequent with genes under control of a *lac*-type promoter. In fact, for some cases, one may find that induction does not increase the constitutive level of expression. This is due in part to the mechanism of repression by the LacI protein. It has been shown that the repressor binds the natural *lac* operator in a DNA region that also contains part of the 5′ coding sequence for LacZ. If this region is exchanged for that of a foreign gene, then the affinity of the repressor for the operator is decreased and transcription can occur at a reduced level.

The optional pLysE or pLysS plasmids for the T7 system should be used with considerable caution. The presence of pLysE leads to a high level of lysozyme in the cell, which can dampen expression and eventually weaken the cell wall. It also, however, brings an additional advantage for purification: a simple freeze-thaw cycle usually effects cell lysis efficiently.

In the case of no detectable expression, we advise (1) trying another promoter system; (2) testing several different host strains; (3) fusing the gene of interest to well-expressed DNA sequences such as LacZ, glutathione transferase (GST), thioredoxin, or protein A, to aid expression and/or recovery (*UNIT 5.1*).

Optimization of codon usage is a topic outside the scope of this unit (Robinson et al., 1984). Overexpression of rare tRNAs and mutagenesis of rare codons have been used for enhancing expression of heterologous proteins in *E. coli* (De Boer and Hui, 1990).

DNA used for electroporation should be as free of salts as possible, as they contribute to decreasing the resistance of the sample and can lead to arcing. It is quite useful to make large batches of competent cells (e.g., 800-ml cultures) and freeze them in aliquots. Several host strains can be transformed quickly (in 2 hr) tested in parallel for expression. It should also be stressed that the goal of the transformation is only to obtain a few colonies of *E. coli* cells carrying the expression vector. Efficiency is not a major concern. Usually a few hundred transformant colonies are generated; only a small proportion is tested for the ability to express the recombinant protein of interest.

SDS-PAGE analysis of total *E. coli* cell proteins is straightforward and reproducible. One minor difficulty may arise from pellet sample preparation—if DNA has not been broken down well enough at the sonication step, the sample will be highly viscous and hard to load on the gel. In this instance, sonication should be repeated. At low levels of expression, it is possible that Coomassie staining will not be sensitive enough. It is not recommended that more sensitive staining methods (e.g., silver staining) be tried, as this will only increase the background. Rather, immunoblotting should be used to analyze the proteins. It is also good practice to include negative controls, such as noninduced cell extract or extract of induced cells carrying an empty vector, as well as positive controls, such as samples from previous experiments or partially pure protein where available.

Anticipated Results

Expression levels of the desired proteins may range from <1% to >40% of total cell protein. In shaker-flask cultures this is equivalent to hundreds of milligrams per liter, which can be increased to grams-per-liter level in

BSU IASRI CENTRAL UNIVERSITY LIBRARY

fermenters (where greater cell densities are achieved; see *UNIT 5.3*). The expressed product can usually be visualized by running appropriate extracts of cells on SDS-polyacrylamide gels and staining with Coomassie blue. The majority of the proteins produced will be insoluble, but the material can often be solubilized and renatured to an active state (*UNITS 6.3, 6.4, & 6.5*).

Time Considerations

Transformation of cells requires about 1 day. Cell growth, induction, and harvesting take 6 to 8 hr depending on the expression system and strain of *E. coli.* Analyzing plasmid stability if necessary extends into the following day. It is often convenient to conduct analysis of samples by SDS-PAGE the next day, as gel preparation, running, staining, and destaining will require several hours. The requirement to prepare overnight cultures to be induced or analyzed must also be taken into account. Gel preparation can be avoided by using commercially available gels (e.g., Phast-gels from Pharmacia Biotech or minigels from Novex). Overall, 2 to 3 days should be required for full testing of a given expression vector in different host strains.

Fermentation and Growth of *Escherichia coli* for Optimal Protein Production

Large-scale production of recombinant proteins in *Escherichia coli* requires growth of cells in fermentors. Fermentation involves the transformation of simple organic compounds by the enzymatic machinery of *E. coli*, in this case to produce proteins. There are many choices of bacterial strain, vector, expression system, and protein localization and purification strategy that must be set before proceeding to batch fermentation. *UNIT 5.1* gives an overview of protein expression in *E. coli*, and *UNIT 5.2* outlines procedures for transforming cells and inducing synthesis of foreign proteins in various expression systems on a small scale in shaker flasks. Table 5.2.1 lists *E. coli* strains appropriate for use in fermentors. The Commentary of this unit discusses important characteristics of fermentation equipment.

Starting with a strain of *E. coli* that has been transformed to produce the desired protein (*UNIT 5.2*) this unit focuses on production of recombinant proteins in batch fermentations (Basic Protocol 1). Alternate protocols introduce variations of fermentation systems that enable continuous growth and protein production in high-cell-density, fed-batch cultures (Alternate Protocol 1) and that permit labeling of recombinant proteins with heavy atom derivatives such as selenomethionine (Alternate Protocol 2) or with stable isotopes such as ^{2}H, ^{13}C, and ^{15}N (Alternate Protocol 3). Production of labeled proteins facilitates structural studies by X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy. The protocols in this unit are designed for expression systems directing intracellular or periplasmic localization of recombinant proteins; however, in the case of extracellular secretion of the desired protein, the culture medium itself, rather than pelleted cells, would be saved, concentrated, and subjected to purification processes.

Fermentation experiments require careful monitoring of cell growth and assurance of preinoculation sterility, which are described in Support Protocols 1 and 2, respectively. It must be kept in mind, however, that the outcome of fermentation experiments, even if derived from successful small-scale shaker flask cultures (*UNIT 5.2*), may be negatively affected by unexpected toxicity of the target protein in fermentation systems.

PRODUCTION OF RECOMBINANT PROTEINS IN BATCH FERMENTATIONS

BASIC PROTOCOL 1

This protocol describes the basic sequence of operations, their timing, and the key issues associated with batch fermentations. Simple batch fermentations involve growth of fermenting organisms in a fixed amount of medium, without additional nutrients. The fermentor is set up, filled with fermentation medium (but not including heat-sensitive ingredients), and sterilized. Filter-sterilized heat-sensitive ingredients are then added, and environmental parameters are set to the desired values (using acid and base to adjust pH) before final preinoculation samples are taken to check sterility (Support Protocol 2). An inoculum prepared from a fresh overnight culture of the transformed *E. coli* strain is introduced into the fermentor and the cells allowed to grow. Synthesis of the recombinant protein following induction of cells is monitored, and cells are harvested by centrifugation using a batch pot or continuous feed centrifuge, depending on the volume of medium processed.

Special fermentation equipment is required. Several commercial manufacturers produce fermentation equipment (Table 5.3.1) for laboratory use (1 to 20 liters) or small pilot-scale experiments (50 to 200 liters). For recombinant *E. coli* processes, users should pay particular attention to heat and oxygen transfer, process monitoring and control (particu-

larly if high-cell-density processes are needed; Alternate Protocol 1), and ease of maintenance and servicing. Utilities such as air, water, steam, and electricity are needed in defined qualities and quantities. Consult the fermentor manufacturer for specific requirements.

Materials

Transformed *E. coli* host strain expressing the protein of interest (*UNIT 5.2*)
LB medium with antibiotic (*UNIT 5.2*)
Antifoam: polypropylene glycol (PPG) 2000 (pure; store indefinitely at room temperature)
Nutrient solution (optional, for fed-batch methods; see Alternate Protocol 1)
ECPM1 medium (see recipe)
85% (w/v) H_3PO_4
28% (w/v) NH_4OH
10 N NaOH

Fermentor (Fig. 5.3.1)
5-ml and 50-ml sterile syringes and 1 × 40–mm needles
Centrifuge, with capacity up to 6 liters per run (for 1- to 10-liter scale; e.g., Sorvall RC3B, equipped with H6000A rotor) or continuous feed centrifuge (for scale >10 liters; Fig. 5.3.2; e.g., Sharples AS16)
Heat-sealable plastic bags and heat-sealing apparatus

Additional reagents and equipment for inducing protein expression and for preparing samples for polyacrylamide gel analysis (*UNIT 5.2*)

Prepare the inoculum and fermentor

1. Prepare an overnight culture of the transformed *E. coli* host strain expressing the protein of interest by inoculating a suitable amount of LB medium, supplemented with the appropriate antibiotic to maintain plasmid-carrying cells, with a single colony picked from an LB/antibiotic plate or retrieved from a vial of frozen cells (see *UNIT 5.2*). The next morning, read the OD_{600} against water as a blank to verify that the

BU IASI CENTRAL UNIVERSITY LIBRARY

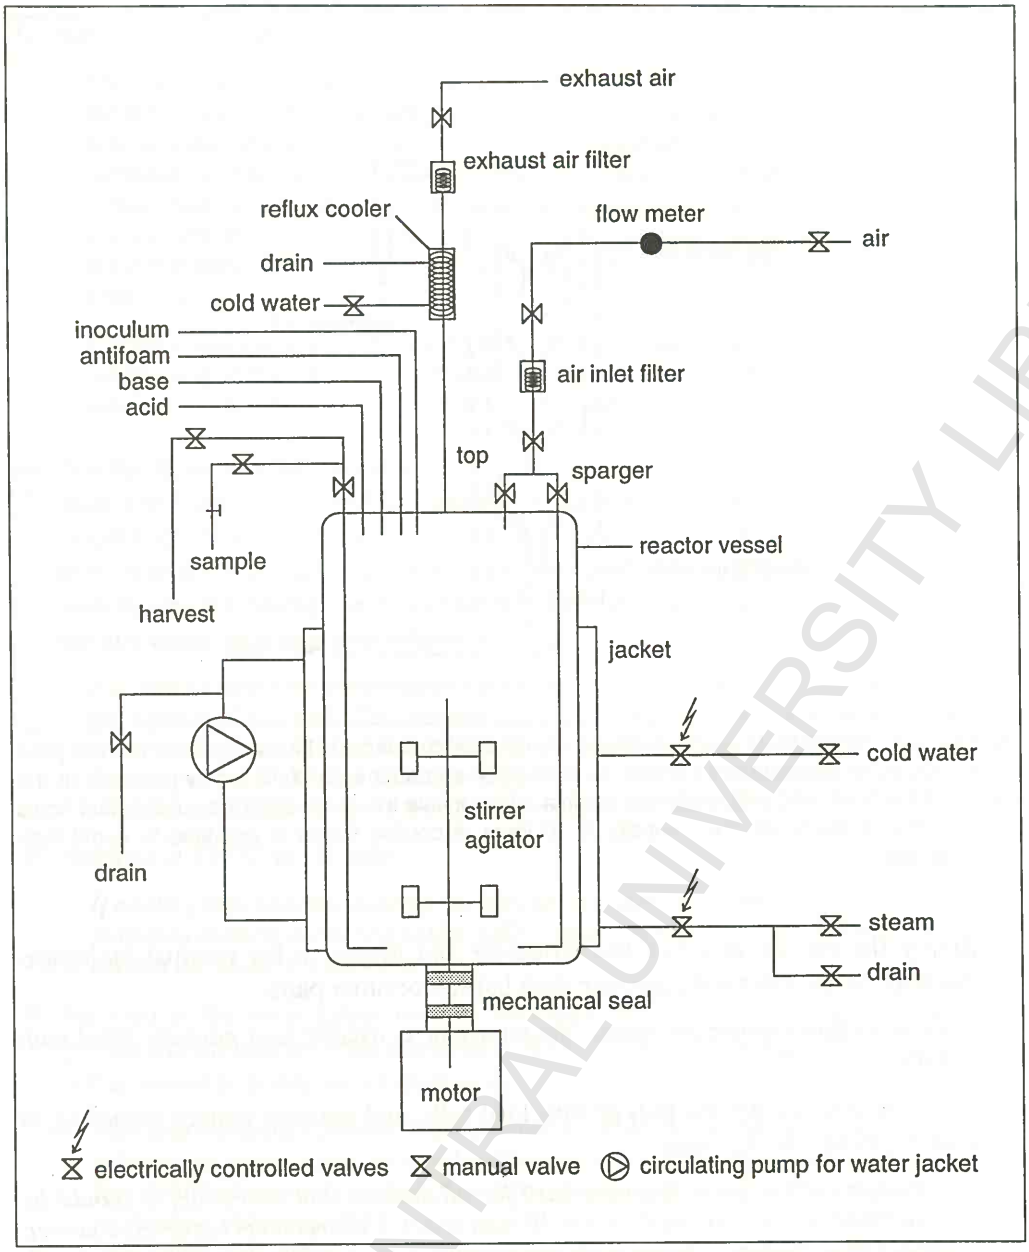

Figure 5.3.1 Schematic diagram of a bacterial fermentor, depicting major functions. Variations in the design can be made to suit specific requirements.

culture has reached stationary phase (i.e., OD>1.5, see Support Protocol 1). Use the overnight culture to inoculate the fermentor.

The size of the inoculum can be varied between 1% and 10% of the intended fermentation volume. For a 10-liter fermentor, the required inoculum of 100 to 1000 ml can be conveniently prepared in 500-ml to 5-liter shaker flasks (a maximum ratio of liquid/flask volume of 0.3 ensures that the culture is well aerated). Fermentors of sizes above 10 liters can be inoculated with several shaker flasks, representing 1% of the fermentor volume. The contents of all the inoculum flasks are pooled into a single large sterile container, fitted with the appropriate transfer line.

The choice of antibiotic is dictated by the transformation vector, and the incubation temperature depends on the expression system (use 30°C for p_L-based systems and 37°C for others). The inoculum is needed in step 15 after the fermentor has been loaded with fermentation medium and sterilized.

BOULDER CENTRAL UNIVERSITY LIBRARY

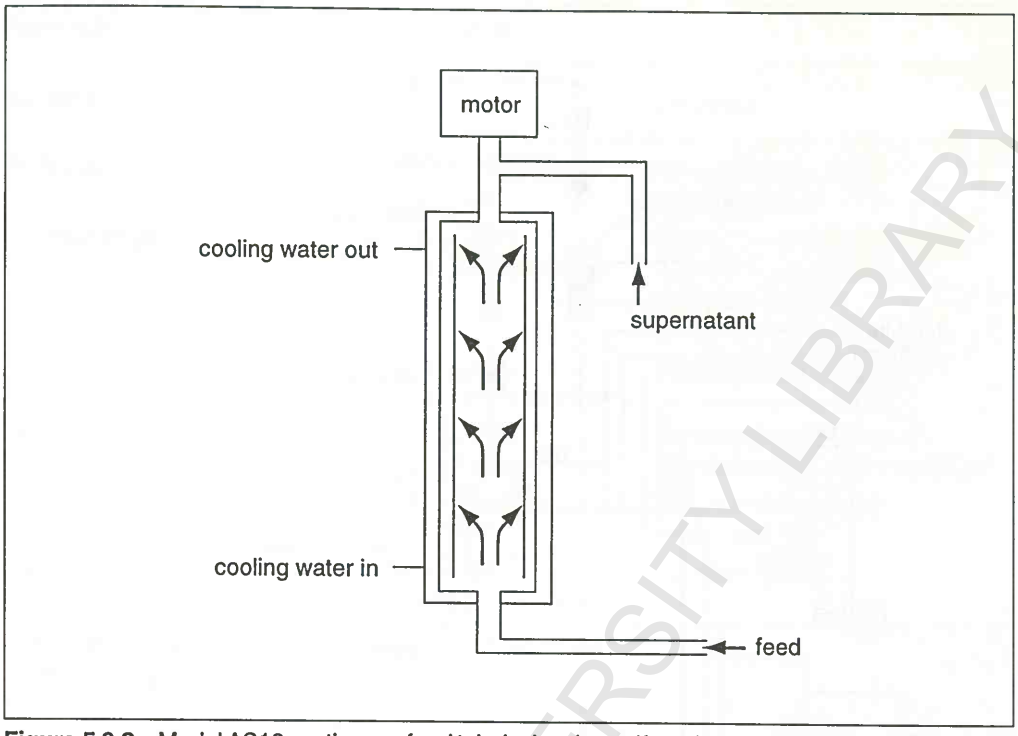

Figure 5.3.2 Model AS16 continuous feed tubular bowl centrifuge (Alfa Laval). Other models (disc stack, with pellet ejection) are suitable for pilot-scale operations. Broth is fed by pressure at the bottom of the bowl, and cells sediment against a liner inside the bowl. Cell-free supernatant flows from the top of the bowl. The capacity is ~6 liters. A cooling jacket is provided to avoid high temperatures.

2. Empty the reactor vessel of the fermentor and inspect it for residual biological material on the inner wall, agitator shaft baffles, or other parts.

   Between fermentation processes, the fermentor is usually kept partially filled with water.

3. Calibrate sensors: pH and pO_2 probes, load cells, and pressure gauges according to manufacturer's instructions.

   Although calibration is not necessary for all sensors and every run, it should be performed on a regular basis (every 10 runs or so). The pH and pO_2 probes, however, should be recalibrated before each run because of the possible drift of the signal with time or fouling of the probe membrane.

   The calibration of the pO_2 probe done here is a rough determination of whether the probe is responding to changes of dissolved O_2. The precise calibration for pO_2 is performed at step 10, after the probe is in the sterilized fermentation medium, in an environment closest to the one of the process.

4. Prepare accessory lines, transfer vessels, and ports, including septums and addition lines for inoculum, acid, base, antifoam, nutrients, and inducers. Sterilize by autoclaving. Also sterilize antifoam and, if applicable, nutrient solution, if possible while linked to the respective lines.

   Some nutrient solutions (e.g., for fed-batch processes) contain heat-sensitive components and should be sterilized according to the recipe (see Reagents and Solutions).

5. Prepare ECPM1 medium by mixing all heat-sterilizable ingredients with water to ~80% of the final volume. Pour into fermentor.

   For fermentation volumes exceeding 5 liters, dissolve all ingredients as a concentrate (at 100× the final required concentration) and pour into the fermentor.

BJU IASI CENTRAL UNIVERSITY LIBRARY

6. Adjust presterilization volume by adding water directly to the reactor vessel.

The presterilization volume should be calculated from the final culture volume (which should not exceed ¾ of the total fermentor volume) by deducting volumes of inoculum, heat-sensitive ingredients and antibiotic to be added and water that evaporates during sterilization. The addition of water resulting from steam condensation during sterilization must also be taken into account. The amounts of liquid loss or gain should not exceed 10% of the final culture volume and is best empirically determined by measuring accurately the liquid level pre- and post-sterilization in a mock trial sterilization with water.

Culture volume does vary during the process, due to mass cell accumulation, sampling, additions of inducers and for pH and foam correction, but these phenomena usually result in a net volume variation that is negligible (except for fed-batch processes).

Sterilize the fermentor and medium

7. Start sterilization cycle. For autoclavable glass transfer vessels (usually 1 to 5 liters), disconnect all cables and tubings from the fermentor; allow the inside of the chamber to be ventilated through one or two lines (protected with air filters) that communicate with the reactor headspace. For transfer vessels that can be sterilized in situ, engage the automatic sequence controller.

It is best to insert the temperature sensor of the autoclave into the temperature port of the reactor, if possible. This ensures that the autoclave control system will sense the exact temperature of the broth inside the reactor. For in situ sterilizable vessels, most fermentors are fitted with an automatic sequence controller that initiates and controls the whole sterilization cycle with predetermined parameters.

8. Sterilize at 121°C for 30 min.

If cooling proceeds too quickly, an internal vacuum may form that will open the way to contamination. A cooling rate of ≤40°C/min is acceptable—if it is higher than this, restrict the cooling water flux.

9. As soon as the temperature reaches the range of 102° to 108°C, apply headspace pressure to the reactor with sterile air (0.05 to 0.1 bar). Start water flow through the reflux cooler to condense exhaust gases.

Applying headspace pressure is important to avoid an internal vacuum and to create a barrier to any potential external contaminant. It is also good practice, once pressure has stabilized, to set a small air flow through the headspace (0.2 liters air/culture/min) to dry the exhaust gas filter.

Conduct final preparations for inoculation

10. For pH correction, pour 85% H_3PO_4 into one transfer vessel (acid) and 28% NH_4OH into the other (base) under a biological hood. Connect acid, base, and antifoam lines aseptically to the fermentor. Once the temperature is ≤40°C, proceed to step 11.

Aseptic connections are easily made by using a sterile needle to puncture a sterile septum port. Use flame sterilization and/or a 70% ethanol spray to ensure sterility. Some connectors can be sterilized again by steam after the connection is completed.

11. Add heat-sensitive ECPM1 medium ingredients (the 1 M $MgCl_2 \cdot 6H_2O$ previously sterilized by 0.22-µm filtration; see Reagents and Solutions) with a sterile syringe by puncturing a septum port with the needle.

12. Calibrate pO_2 sensor by sparging air at 0.5 vol gas/vol culture/min with vigorous agitation (≥500 rpm) and adjusting the 100% saturation point.

The zero point of the sensor can be calibrated by sparging N_2 gas instead of air, or with a sensor simulator, but this point should not need frequent recalibration—after every 10 sterilization cycles should suffice.

BOKU - IAM - UNIVERSITÄTSBIBLIOTHEK

13. Adjust all environmental parameters to the desired set points.

Typical parameter settings are: temperature, 30° or 37°C; pH, 7.0; agitation, 300 rpm; air flow, 1 vol/vol culture/min; pO_2, 100% air saturation.

14. Withdraw a small sample aseptically and check for sterility (see Support Protocol 2).

A sterile fermentor can be prepared 2 to 3 days in advance. If this is done, it is best to recheck the sterility of a fresh sample taken just before inoculation. Because the results of this sterility check are not known for another 12 to 16 hr, the procedure is initiated and continued. In case of a contamination revealed after inoculation, the batch should be considered suspect and/or discarded. A massive contamination (which could occur if the fermentor has been prepared more than 24 hr in advance) will be obvious from the evolution of the pH and/or pO_2 and turbidity of the sample. If any contamination is detected before inoculation, the entire run should be cancelled and the fermentor cleaned (see step 24).

Inoculate the fermentor, growth cells, and induce protein expression

15. Aseptically connect inoculum line to fermentor septum port. Inoculate fermentor by transferring the inoculum (step 1) aseptically into the reactor vessel. Disconnect inoculum line.

A short spray of 70% ethanol on the septum and needle improves sterility.

Inoculation is achieved either via an in-line peristaltic pump or by pressurizing the inoculum vessel with sterile air.

16. Monitor growth by measuring OD_{600} of samples taken at 1-hr intervals (see Support Protocol 1). When the target cell concentration is reached, proceed to induction.

Target cell concentration depends on the strain and expression system. As a general rule, and in the absence of any previous experience with a given strain, a target of OD 5 to 10 is applicable. It is possible, however, that the same process can also be run with induction at a later stage (OD 15 to 20), but this needs empirical determination.

17. Induce protein expression via temperature or chemical induction using one of the following methods, as appropriate.

    a. *For the p_L system:* Perform a fast temperature shift (within a few minutes) from 30° to 42°C and incubate 5 hr.

    b. *For the trp* promoter system: Add IAA to a final concentration of 25 mg/liter (see *UNIT 5.2*). Incubate to stationary phase (usually overnight).

    c. *For the lac and tac promoter and T7 systems:* Add IPTG to a final concentration of 0.5 to 1.0 mM (*UNIT 5.2*) and incubate 5 hr.

18. At 1-hr intervals, withdraw samples of the culture, monitor growth by OD_{600} measurements, and prepare them for polyacrylamide gel analysis, as described in *UNIT 5.2*, to monitor recombinant protein expression.

A band of the expected molecular weight should appear in lanes of induced samples, but not in those of uninduced or early-time-of-induction samples. Results of this analysis cannot be known before the projected harvesting time, so for the first experiment, the process should be run with the time lines indicated above. The best combination of high expression (judged by band intensity on the gel) and high cell density should dictate optimal harvesting time—these conditions can then be applied to repeat experiments.

It it also important to monitor growth closely during the induction phase because some strains rapidly lyse. In case of cell lysis, proceed to harvesting.

PSU IASL / CENTRAL UNIVERSITY LIBRARY

Harvest the cells

For small fermentors (1 to 10 liters):

19a. To harvest cells from small fermentors, pressurize the fermentor and transfer the reactor contents into an intermediate container.

20a. Distribute liquid culture, preferably under a biological hood, into centrifuge bottles. Record final culture volume in order to estimate final cell yield.

Aerosols should be minimized at all times. Use closed containers fitted with sterile filter vents.

21a. Centrifuge 15 min at 5000 × *g* (4000 rpm in an H6000A rotor), 4°C.

22a. Collect pellets from each centrifuge bottle and place together in a heat-sealable plastic bag. Proceed to step 23.

If the protein is secreted to the extracellular medium, collect the supernatant and concentrate by tangential flow ultrafiltration.

For large fermentors (>10 liters):

19b. For larger fermentors, prepare for cell harvest by removing all flexible tubing connections on the reactor, stopping pH and pO_2 control loops, and setting the temperature set point at minimum. Set pressure set point to 0.8 bars and direct gas flow to the headspace of the reactor.

In Figure 5.3.2, the broth is transferred from the fermentor to the bottom of a continuous feed centrifuge by pressurizing the reactor through the headspace. Consult the manufacturer's instructions for specific operating conditions. It is important to cool the culture liquid quickly to minimize proteolytic degradation.

20b. Start the continuous feed centrifuge and accelerate to an effective centrifugation force of ≥10,000 × *g*. When bowl speed is stable, open connecting valves from the fermentor to the centrifuge.

21b. Set inlet flow rate to the centrifuge at ~1 to 2 liters/min. Centrifuge at 4°C until all the medium has been processed.

22b. Stop centrifuge, dismount the bowl, and collect the pelleted cells into a heat-sealable plastic bag.

If the purification process cannot handle the entire pellet volume, divide the material into smaller aliquots.

If the protein is secreted to the extracellular medium, collect the supernatant and concentrate by tangential flow ultrafiltration.

Store the harvested cells and clean the fermentor

23. Retain a small amount of the pellet (50 to 100 mg) in a separate microcentrifuge tube for polyacrylamide gel analysis (step 18) to verify that centrifugation has not altered the target protein expression level. Close pellet-containing bags by heat sealing. Record total pellet weight and freeze at –20°C.

Most recombinant proteins in the pelleted cells remain stable for months when stored at –20°C. However, some membrane receptors (e.g., neurokinin, adrenergic, transmembrane receptors in general) are best preserved by snap freezing in dry ice/isopropanol and storing at –70°C.

24. To clean the fermentor, fill it with water and adjust to pH 11.0 to 12.0 by adding 10 N NaOH. Set temperature to 50°C and leave with vigorous agitation overnight.

Local biosafety rules may require sterilization of the reactor before cleaning. For

BCU ARCHIVE CENTRAL UNIVERSITY LIBRARY

sterilization, fill the reactor with water and proceed to steps 7 and 8. If the fermentor is still not clean after this treatment, alternate alkali and acid (H_3PO_4) treatments.

25. Empty the reactor, rinse extensively with water, and sterilize as described in steps 7 and 8. Prepare the fermentor for another run, if desired.

Electrochemical sensors (pH, pO_2, pCO_2) should be removed and stored according to manufacturer's instructions. The fermentor should then be filled with water, sterilized, and stored sterile until the next run.

ALTERNATE PROTOCOL 1

PROTEIN PRODUCTION IN HIGH-CELL-DENSITY PROCESSES: FED-BATCH METHODS

Fed-batch fermentations take advantage of the high-protein-synthesizing capacity of an exponentially growing culture while minimizing the buildup of toxic by-products by keeping growth carbon source–limited. This protocol describes a simple glycerol-supplementation method that is applicable to a wide range of culture conditions. Cells are first grown in a batch fermentation in a medium containing 10 g/liter glycerol. After the initial glycerol is consumed, the culture is supplemented with an increasing feed rate of concentrated medium containing 900 g/liter glycerol. Except for cell density, induction of protein synthesis and harvest are the same as for batch fermentation (see Basic Protocol 1).

Additional Materials (also see Basic Protocol 1)

HCDF1 medium (see recipe)
HCDM1 medium (see recipe), containing 10 g/liter glycerol
O_2 gas, pure

1. Prepare an inoculum culture of the transformed *E. coli* host strain expressing the protein of interest, then set up the fermentor as for batch fermentation (see Basic Protocol 1, steps 1 to 4).

2. Prepare HCDF1 feed medium in a feed tank (transfer vessel) and set on a balance or a load cell to keep track of feed consumption.

3. Proceed to preparing the fermentation medium, sterilizing the medium and fermentor, and conducting the final preparations for inoculation for batch fermentation procedure (see Basic Protocol 1, steps 5 to 14), substituting HCDM1 batch medium containing 10 g/liter glycerol as the fermentation medium.

4. Inoculate the fermentor and grow cells (see Basic Protocol 1, steps 15 and 16). After the initial glycerol is consumed, start the feed of HCDF1 medium.

A sharp rise in pO_2 is indicative of reduced oxygen consumption and thus of glycerol becoming limiting. Monitor growth during this phase to estimate maximum growth rate (see Sinclair and Cantero, 1990, for methodology).

5. Increase rate of addition of HCDF1 medium gradually and withdraw samples to follow the increase in OD_{600}. Adjust rate of HCDF1 medium addition to the target feed rate. Monitor feed rates by measuring the mass of the feed tank over time.

The target feed rate can be estimated as

$$F = \mu \times Vf \times OD/(Y \times 0.4 \times 0.9)$$

where F is the feed rate (ml/hr), μ is the target growth rate (hr^{-1}), Vf is the fermentor volume (liters), OD is the optical density at 600 nm, Y is the yield of cell mass per unit carbon source (g/g), 0.4 represents the conversion factor from OD to cell mass (OD/g/liter), and 0.9 is the glycerol content in the feed solution (g/ml). An estimate of

BU IASI / CENTRAL UNIVERSITY LIBRARY

80% of the maximum growth rate (step 4) is a good starting value. An estimate of 0.3 is a good value for the yield, Y.

When monitoring feed rates, make sure to take into account the density of the feed and the increase in fermentation volume with feeding. The target growth rate is dependent on each strain and each process. To avoid accumulation of toxic by-products (organic acids), the target growth rate should be set below 80% of the maximum growth rate observed during the batch phase.

6. Blend pure O_2 gas into the air that is sparged into the reactor (either by solenoid valve pulses or by a motor-driven proportional valve) to make sure that pO_2 is properly controlled (set point between 20% and 50%).
7. Once the target high biomass density is obtained (OD_{600} above 50), induce expression of the protein as in batch fermentation procedure (see Basic Protocol 1, step 17).

   Final cell densities can be as high as 100 to 150 OD units.

   Induction by a chemical inducer can also be achieved by simply adding the inducer to the feed solution (gradual induction).
8. Proceed to monitoring expression and harvesting (see Basic Protocol 1, steps 18 to 23) while continuing to match the rate of HCDF1 supplementation with growth.

IN VIVO LABELING OF RECOMBINANT PROTEINS WITH HEAVY METAL DERIVATIVES

ALTERNATE PROTOCOL 2

To maximize incorporation of selenomethionine in place of methionine in recombinant proteins to facilitate structural studies, it is preferable to use a methionine auxotroph host strain. The protocol is best suited for small fermentors (1 to 10 liters) because the medium change step requires sterile harvesting via a batch pot centrifuge.

Additional Materials (also see Basic Protocol 1)

Methionine auxotroph host strain: *E. coli* DL41 or B834 (Table 5.2.1)
Expression vector containing gene for the protein of interest
DLM medium (see recipe)
Complete rich medium (e.g., LB medium; *UNIT 5.2*)

Additional reagents and materials for electroporation and testing expression of transformants (*UNIT 5.2*)

Construct the expression strain

1. Transform methionine auxotroph host strain with expression vector containing the gene for the protein of interest (see *UNIT 5.2*).

   For T7 expression systems, use E. coli B834 (with or without pLys plasmid) as a host (also see UNIT 5.2 Commentary and see Table 5.2.1).
2. Test expression of transformants in a shaker flask induction test (see *UNIT 5.2*).

Set up the fermentation and induce protein expression

3. Prepare DLM medium (same volume as fermentor) and keep at room temperature.
4. Prepare fermentor with complete rich medium and inoculate with the recombinant strain (see Basic Protocol 1, steps 1 to 16).
5. Grow overnight in rich medium at 30°C for p_L strains, 37°C for others.

B. C. U. „M. [illegible] IAŞI
C H [illegible]

BCU IAŞI CENTRAL UNIVERSITY LIBRARY

6. Withdraw sample and measure OD_{600}. Harvest cells under sterile conditions by batch pot centrifugation (see Basic Protocol 1, steps 19a to 22a). Stop all control loops on the fermentor.

   OD values should be in the range of 20 to 30 after overnight growth. Harvest only part of the culture. Calculate the volume to be harvested so that, once the cells are resuspended in the same volume of DLM labeling medium, the OD_{600} will be between 10 and 15.

7. Resuspend the pellet in DLM medium. Transfer to a sterile container and then back to the fermentor. Resume all control loops.

   In practice, there will be several pellets, distributed in several centrifuge bottles. Pellets are individually resuspended, then suspensions are pooled into a single vessel to avoid having to transfer each separate bottle back into the fermentor. Remember that sterility is a must here, and handling one container is less risky than dealing with several.

8. Wait for 30 min until all environmental parameters are back to their set points and are stable before inducing expression (see Basic Protocol 1, step 17). Proceed to monitoring expression and harvesting cells (see Basic Protocol 1, steps 18 to 23).

ALTERNATE PROTOCOL 3

STABLE ISOTOPIC LABELING OF RECOMBINANT PROTEINS

Uniform incorporation of stable isotopes in recombinant proteins is an alternative to selective labeling of a given amino acid (Alternate Protocol 2) to facilitate structural studies. The method requires the use of a semi-defined medium containing salts, trace elements, and yeast extract. Cells are supplied with [^{13}C]glucose, $^{15}NH_4Cl$, and/or D_2O, and induced to synthesize recombinant protein labeled with ^{13}C, ^{15}N, and/or ^{2}H. The three labels can be used individually or in combination. This protocol makes use of the fed-batch method (Alternate Protocol 1) but substitutes (labeled) glucose for glycerol as the carbon source and is run at much lower cell densities.

Additional Materials (also see Basic Protocol 1)

Transformed *E. coli* host strain expressing the protein of interest (*UNIT 5.2*)
HCDM1 medium (see recipe)
50% (w/v) [^{13}C]glucose
100 g/liter $^{15}NH_4Cl$ stock solution
D_2O
Base for pH correction: 2 N NaOH (for ^{15}N label)

1. Grow an inoculum culture of the transformed *E. coli* host strain expressing the protein of interest, then prepare fermentor and start the batch fermentation with HCDM1 medium (see Basic Protocol 1, steps 2 to 14), setting up 50% [^{13}C] glucose as the nutrient solution (place feed tank on a balance or load cell).

   In this protocol, the carbon source is labeled glucose instead of glycerol.

   For ^{2}H labeling, use D_2O instead of H_2O in making up HCDM1 medium.

2. After medium sterilization add 10 g/l [^{13}C]glucose and the first 5-ml portion of 100 g/liter $^{15}NH_4Cl$ stock solution per liter fermentation volume (using a sterile syringe; see Basic Protocol 1, step 12).

   Glucose is added after sterilization to avoid partial destruction when heat sterilized with nitrogen-containing compounds present in the medium. To achieve the target 10 g/liter concentration, add 40 ml of the feed solution per liter of culture.

BU IASI / CEN / PAL - UNIVERSITY LIBRARY

$^{15}NH_4Cl$ is added in three separate batches to avoid inhibition by growth by excess NH_4Cl in the medium.

3. Inoculate fermentor (see Basic Protocol 1, step 15). Allow cells to grow. When the initial [^{13}C]glucose is consumed, start feed with [^{13}C]glucose.

   A sharp rise in pO_2 is indicative of glucose becoming limiting and thereby reducing oxygen consumption. To set initial and subsequent feed rates, use the equation in Alternate Protocol 1, step 5, substituting 0.5 for 0.9 as the glucose feed content (g/ml), using a target growth rate of 0.3/hr and an estimate of 0.4 for the yield Y.

4. Monitor growth by withdrawing samples periodically and measuring OD_{600}. At an OD_{600} ~5, add second batch of $^{15}NH_4Cl$ and induce protein expression (see Basic Protocol 1, step 17).

   In this protocol a high cell density is not desirable, and therefore no pure O_2 should be necessary for pO_2 control.

5. At 1 hr postinduction add the last batch of $^{15}NH_4Cl$.

6. Proceed to monitoring protein expression and harvesting (see Basic Protocol 1, steps 18 to 23) while continuing to match the rate of glucose supplementation with growth.

GROWTH MONITORING

SUPPORT PROTOCOL 1

Bacterial growth can be monitored off-line by several different methods (Lech and Brent, 1994a). For fermentation process control, spectrophotometry is fast, reliable, and simple. Microscope counting is an alternative but is more cumbersome and time-consuming. On-line sensors also exist and have been used successfully in some cases (Schügerl et al., 1993). Most sensors, however, are sensitive to particulate matter, gas bubbles, fouling, and calibration drifts.

Materials

Test sample (e.g., *E. coli* inoculum or fermentation medium)
Culture medium (optional, for diluting visibly turbid cultures)

Spectrophotometry cuvettes (e.g., 1-cm light path)
Fixed-wavelength spectrophotometer (e.g., 600 or 660 nm)
Count slide *or* hemacytometer
Phase-contrast microscope (400×)

For spectrophotometry:

1a. Place test sample in spectrophotometry cuvette. Fill reference cuvette with water.

2a. Transfer cuvettes to a fixed-wavelength spectrophotometer and measure the optical density at 600 nm.

   The level of absorbance at 600 nm will depend on the distance between the cuvette and the detector and will vary among instruments, often by a factor of 2. It is thus wise to calibrate each instrument by recording the OD_{600} of a culture that contains a known number of cells determined by some other method, such as observation on a count slide or titering for viable colonies (Lech and Brent, 1994b).

   For a culture grown in rich medium, a good rule of thumb is that each 1 OD unit is roughly equivalent to 10^9 cells/ml. OD readings above 0.4 cannot be accurately correlated with cell numbers and the sample should be diluted 10- or 100-fold with PBS to bring reading back into the 0.4 range.

BOWMAN / CENTRAL UNIVERSITY LIBRARY

For cell counting:

1b. Take a clean count slide (or hemacytometer) and cover it with a clean coverslip. Dip a 0.1- or 1-ml pipet into the test sample, allow a small drop of liquid to form on the end of the pipet, and touch it lightly to the surface of the slide at the periphery of the coverslip.

2b. Put the slide on the stage of a phase-contrast microscope set to 100×, and focus on the cells. Calculate cell densities.

Each cell in a small square of a count slide is equivalent to 2×10^7 cells/ml.

SUPPORT PROTOCOL 2

STERILITY CHECKING

Although results are known only after an overnight incubation, checking the sterility of the fermentation medium prior to inoculation is essential to ensure reproducible results and aids in troubleshooting potential problems. To absolutely eliminate contamination during the test itself, it is preferable to perform this protocol under a microbiological hood. A quick check of sterility requires a sample size of 100 µl, whereas more sensitive detection requires up to 100 ml.

Materials

Test sample (e.g., fermentation medium)
LB plates with and without antibiotic (*UNIT 5.2*)

0.45-µm membrane (Millipore, type HA or HC)
Sterile filter holder

For a quick check: Spread 100 µl test sample onto one LB plate and one LB/antibiotic plate. Incubate at 30°C overnight. Inspect for appearance of any colonies.

For a more sensitive detection: Filter up to 100 ml test sample by vacuum aspiration through a 0.45-µm membrane set in a sterile filter holder. Disassemble filter holder and transfer membrane to an LB agar plate, face up. Incubate plate 24 to 48 hr at 30°C. Inspect membrane for appearance of any colonies.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

DLM medium

2.5 g adenine·HCl
2.2 g L-glycine
1.3 g guanosine
1 g L-alanine
1 g L-arginine
0.8 g L-aspartic acid
0.06 g L-cystine
1.3 g L-glutamic acid
0.66 g L-glutamine
0.12 g L-histidine
0.5 g L-isoleucine
0.5 g L-leucine
0.7 g L-lysine
0.2 g L-methionine

continued

PSU IASL CENTRAL UNIVERSITY LIBRARY

0.26 g L-phenylalanine
0.2 g L-proline
0.2 g seleno-L-methionine
4.2 g L-serine
0.46 g L-threonine
0.34 g L-tyrosine
0.46 g L-valine
0.34 g thymine
1 g uracil
20 g glucose
0.75 g NH_4Cl
1.2 g K_2HPO_4
0.4 g $MgCl_2 \cdot 6H_2O$
10 ml trace element solution 1 (see recipe)
H_2O to 1 liter

CAUTION: Seleno-L-methionine, which replaces methionine, is highly toxic.

Dissolve each ingredient one after the other in water, except for L-aspartate, L-glutamate, L-tyrosine, guanosine, thymine, and uracil, which need to be dissolved first in a small amount of 0.1 N NaOH.

Sterilize by filtration through a membrane with 0.22-µm pores. Store at room temperature.

ECPM1 medium

4 g K_2HPO_4
1 g KH_2PO_4
1 g NH_4Cl
2.4 g K_2SO_4
132 mg $CaCl_2 \cdot 2H_2O$
10 ml trace element solution 1 (see recipe)
20 g Casamino Acids (enzymatic hydrolysate; Difco)
3 g yeast extract (Difco)
40 g glycerol
H_2O to 800 ml

Mix ingredients, pour into fermentor, and sterilize by heat (see Basic Protocol 1, steps 5 to 8) adding balance of water to 1 liter in step 6. Add 2 ml of 1 M $MgCl_2 \cdot 6H_2O$ (sterilized by filtration through a membrane with 0.22-µm pores) as directed in step 12 of Basic Protocol 1. Once sterilized, the medium can be stored up to 1 week at 4°C.

HCDF1 medium

900 g glycerol
H_2O to 910 ml
Sterilize by heat
Add 20 ml 1 M $MgCl_2 \cdot 6H_2O$ (sterilized by filtration through 0.22-µm membrane)
Add 70 ml trace element solution 2 (see recipe)

BCU IASRI / CENTRAL UNIVERSITY LIBRARY

HCDM1 medium

10 g K_2HPO_4
10 g KH_2PO_4
9 g $Na_2HPO_4 \cdot 2H_2O$
1.1 g NH_4Cl
9 g K_2SO_4
10 ml trace element solution 2 (see recipe)
2 g yeast extract
H_2O to 800 ml

Sterilize by heat (see Basic Protocol 1, steps 5 to 8), adding balance of water to 1 liter in step 6. Add 2 ml 1 M $MgCl_2 \cdot 6H_2O$ (sterilized by filtration through 0.22-μm membrane; see Basic Protocol 1, step 12). Supplement with carbon source (glycerol or glucose) as indicated in Alternate Protocol 1 and Alternate Protocol 3.

Trace element solution 1

5 g EDTA
0.5 g $FeCl_3 \cdot 6H_2O$
0.05 g ZnO
0.01 g $CuCl_2 \cdot 2H_2O$
0.01 g $Co(NO_3)_2 \cdot 6H_2O$
0.01 g $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$

Dissolve EDTA in 700 ml water. Dissolve each element separately by adding just enough 10 N HCl to bring it into solution. Add each element in solution one after the other to the EDTA solution. Add water to 1 liter. Adjust pH to 7.0 with concentrated NaOH. Autoclave. Store in the dark at 4°C.

Trace element solution 2

5 g EDTA
6 g $CaCl_2 \cdot 2H_2O$
6 g $FeSO_4 \cdot 7H_2O$
1.15 g $MnCl_2 \cdot 4H_2O$
0.8 g $CoCl_2 \cdot 6H_2O$
0.7 g $ZnSO_4 \cdot 7H_2O$
0.3 g $CuCl_2 \cdot 2H_2O$
0.02 g H_3BO_3
0.25 g $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$

Dissolve EDTA in 700 ml water. Dissolve remaining ingredients separately in just enough 10 N HCl to achieve solution and add one after the other to the EDTA solution. Add water to 1 liter. Adjust to pH 7.0 with concentrated NaOH. Autoclave. Store in the dark at 4°C.

COMMENTARY

Background Information

The choice of a strategy for fermentation is based primarily on the type of expression system (see UNIT 5.1). For example, chemical induction (e.g., via *trp*, *lac*, or tac promoters) may be more feasible than temperature induction (e.g., via the lambda promoter) in larger-volume fermentors. The strategy also depends on the final intended use for the protein: immunization and generation of antibodies, structure-function investigations, structural studies, or in vivo assays.

Because the fermentation process (i.e., the media, temperature, pH, and pO_2 used) can affect the solubility and localization of the protein, it should be designed with the purification process in mind (Chapter 6).

Localization of the protein in the *E. coli* cell (cytoplasmic, periplasmic, or secreted in the extracellular medium) is also a prime factor in

BAU IAST / CENTRAL UNIVERSITY LIBRARY

the design of the process. Finally and most importantly, the toxicity of the target protein for *E. coli* is a key determinant in the success of the production. For example, cell lysis has been observed repeatedly when over-expressing proteins of the apolipoprotein family.

Fermentation of recombinant *E. coli* has been developed by many different research groups, and several well-documented processes have been published (Knorre et al., 1991; Strandberg et al., 1991; Yang, 1992; Gram et al., 1994). In general, accurate control of environmental parameters (e.g., temperature, pH, and pO_2) is prerequisite for any production. This will also ensure reproducibility among different batches. Table 5.3.1 summarizes vendors of fermentation equipment that we have used successfully. The list is not meant to be exhaustive, and local supply may vary.

Although most recombinant protein production protocols described in the literature are based on a simple batch type of operation (see Basic Protocol 1), fed-batch methods (see Alternate Protocol 1) allow a more productive use of a given reactor by allowing growth of the culture to a high cell density prior to induction. The principle is to supply increasing amounts of nutrients so as to match exponential growth of the culture while minimizing accumulation of toxic by-products. Growth is made carbon source–limited in order to keep the concentration of residual carbon source low and to maximize yield of recombinant proteins.

Fermentations may also be designed to produce labeled products. The replacement of methionine residues by selenomethionine (SeMet) in proteins (see Alternate Protocol 2) was first suggested as a new strategy to tackle a major hurdle in protein X-ray crystallography, namely, determination of the phases (Yang et al., 1990). The approach consists of using crystals of the SeMet-substituted protein in multiwavelength anomalous diffraction (MAD) experiments, which require access to a synchrotron. The SeMet protein can also be used, however, in fixed-wavelength analysis to provide landmarks (i.e., the heavy atoms of selenium) that facilitate data analysis and resolution of the structure.

Nuclear magnetic resonance (NMR) spectroscopy is used increasingly for determining the three-dimensional structure of proteins (up to 40 kDa) in solution. In conventional NMR techniques, however, proteins, because of their large size, generate spectra with overlapping signals, in particular in the region of $_1H$ resonances. This led several teams to develop a general method for labeling proteins with different stable isotopes such as ^2H, ^{13}C, and/or ^{15}N (see Alternate Protocol 3). Isotopic labeling allows NMR specialists to study heteronuclear coupling and to use powerful two-, three-, and four-dimensional editing of spectra. These techniques greatly facilitate assignment of resonances (for a review, see Clore and Gronenborn, 1994).

Critical Parameters and Troubleshooting

Equipment. For optimal operation, several fermentor characteristics are essential. Heat transfer is best achieved through a double jacket around a stainless steel base. Water flow should be guided in loops around the vessel wall to avoid any dead zones. Steam, if available, is the most efficient means of heating. Heating efficiency is critical for temperature shift inductions, where the broth should be heated from 30° to 42°C in a few minutes. In fact, for fermentors with a working volume >10 liters, there should be provision for direct steam injection to obtain a very quick temperature shift. Cooling requires consumption of cold water, which, in some instances can be recycled. Recycling is most useful for installations where supercold water (–4° to 4°C) is used.

In addition to the essential sensors (i.e., temperature, agitation, dissolved O_2, pH, and foam level), sensors such as gas flow, pressure, load, redox potential, culture fluorescence, and mass spectrometer on exhaust gas (Todd, 1989) can be mounted to monitor the environment. Halling (1990) gives detailed information on basic principles and calibration of the essential monitors and Dusseljee and Feijen (1990) review sensors and process control information.

Dissolved oxygen and O_2 transfer can be controlled by agitation, air flow, gas composition, and headspace pressure. In practice, using high-agitation-rate motors with Rushton turbines and sparging O_2-enriched air allow maximal transfers, but oxygen transfer can still become limiting at high cell densities. The average specific oxygen uptake rate for *E. coli* strains growing at a rate of 0.3 hr–1 in ECPM1 medium at 30°C is around 0.4 g O_2/g cells/hr.

Sterilization is a critical operation that can be hazardous if not properly handled. It should always be carried out according to the instructions of the fermentor supplier. An automatic controller is helpful and considerably limits the risks; it also ensures reproducibility of the operation from one batch to another. Sterility is, of course, a prerequisite for any fermentation

BOURNEMOUTH UNIVERSITY LIBRARY

experiment. Fermentor designs should be checked carefully to ensure that all parts in contact with the culture are properly sterilized by heat. The bottom region of the reactor vessel where the agitator shaft enters the fermentor is critical. Double mechanical seals with lubrication by steam condensates provide an efficient sterility barrier. Magnetically coupled agitation systems are even safer because all seals are static.

Computer control is not absolutely required for most routine purposes. It is helpful, however, for fed-batch processes and for those requiring model-based feedback control from off-line analysis. It also allows extensive data logging and analysis both from the fermentor itself and from peripheral instrumentation (e.g., off-gas analysis, flow injection analyzers).

High-cell-density methods. Fed-batch methods can be classified into two types: (i) growth-linked feeding using process parameters such as pH (Bauer and White, 1976) or pO_2 (Mori et al., 1979) to control the feed of nutrients, and (ii) model-dependent feeding, controlled by a mathematical model of growth (Yee and Blanch, 1992). The first class requires little modification to a batch operation, whereas the second class necessitates on-line computer control. In the latter case, one needs to estimate growth from off-gas measurement (Reiling et al., 1985) or by real-time measurement of growth by spectrophotometry. The feed rate can be adjusted via computer control to match the increase in growth monitored by OD_{600}. As high cell densities are obtained, limitations eventually arise from broth viscosity, oxygen transfer, or the cooling capacity of the fermentor. Figure 5.3.3 illustrates a typical fed-batch process run according to Alternate Protocol 1, with a recombinant *E. coli* strain and without induction of expression.

Isotopic labeling. As an alternative to the defined medium described in Alternate Protocol 3, a commercial medium (Celtone) is available from Martek with labeled amino acids derived from unicellular algae. Celtone gives higher cell densities and is inexpensive and easy to make. To use this medium, follow Basic Protocol 1 for growth and induction, use 5 N NaOH for pH control when labeling with ^{15}N, and add another 1× concentration of Celtone medium (100 ml of 10× stock solution per liter fermentation volume) at the start of induction.

Harvesting. Harvesting can be achieved by tangential flow microfiltration as an alternative to continuous centrifugation (Bailey et al., 1990). Tangential flow microfiltration allows the operation to be more contained, but requires a final centrifugation to obtain a cell cake. However, it can also be coupled to cell wash, diafiltration, buffer exchange, and cell breakage by continuous-flow high-pressure homogenizers.

The most common problem found in scaling up from shaker flask experiments is the decrease in expression level. In this case, one can vary the time of induction, check plasmid stability (*UNIT 5.2*), and test other host/vector combinations. Changing the composition of the medium may also solve the problem but is lengthy and labor-intensive. The absence of cell lysis should be confirmed by frequent microscopic observations, and cells must be quickly harvested as soon as lysis begins.

Sterility check. Because the results of this test are not known for 12 to 16 hr, the procedure is initiated and continued. In case of a contamination revealed after inoculation, the batch should be considered suspect and/or discarded. A massive contamination (which could occur if the fermentor has been prepared more than 24 hr in advance) will be obvious from the evolution of the pH and/or pO_2 and turbidity of the sample. If any contamination is detected before inoculation, the entire run should be cancelled and the fermentor cleaned (see Basic Protocol 1, step 24).

Anticipated Results

With an average level of expression (e.g., 10% to 15% of total cellular proteins), a normal batch process will yield ~100 g wet cell pellet per liter, containing ~500 mg of the recombinant protein. This shows that even small-scale fermentations (1 to 10 liters) are quite effective in providing the starting material for purification developments. For actual production, a fed-batch process is more typically used—this maximizes fermentor output, but also requires more manpower to operate. In this case, overall yields of 1.5 to 2 g recombinant protein per liter culture, in the crude extract, are expected.

Time Considerations

Preparation of a fermentor and its ancillaries can be done in 4 to 5 hr. Preparation of the inoculum can be started after that, allowing an overnight test for reactor sterility. The following morning inoculation can proceed, and the fermentation should be completed within 24 to 36 hr. Harvesting takes 1 to 2 hr. Analysis requires an additional 3 hr. While running the analysis, the fermentor can be cleaned, sterilized with water, and made ready for another run. Overall, a complete cycle takes 2.5 to 3 days.

BOU IAS/CERN UNIVERSITY LIBRARY

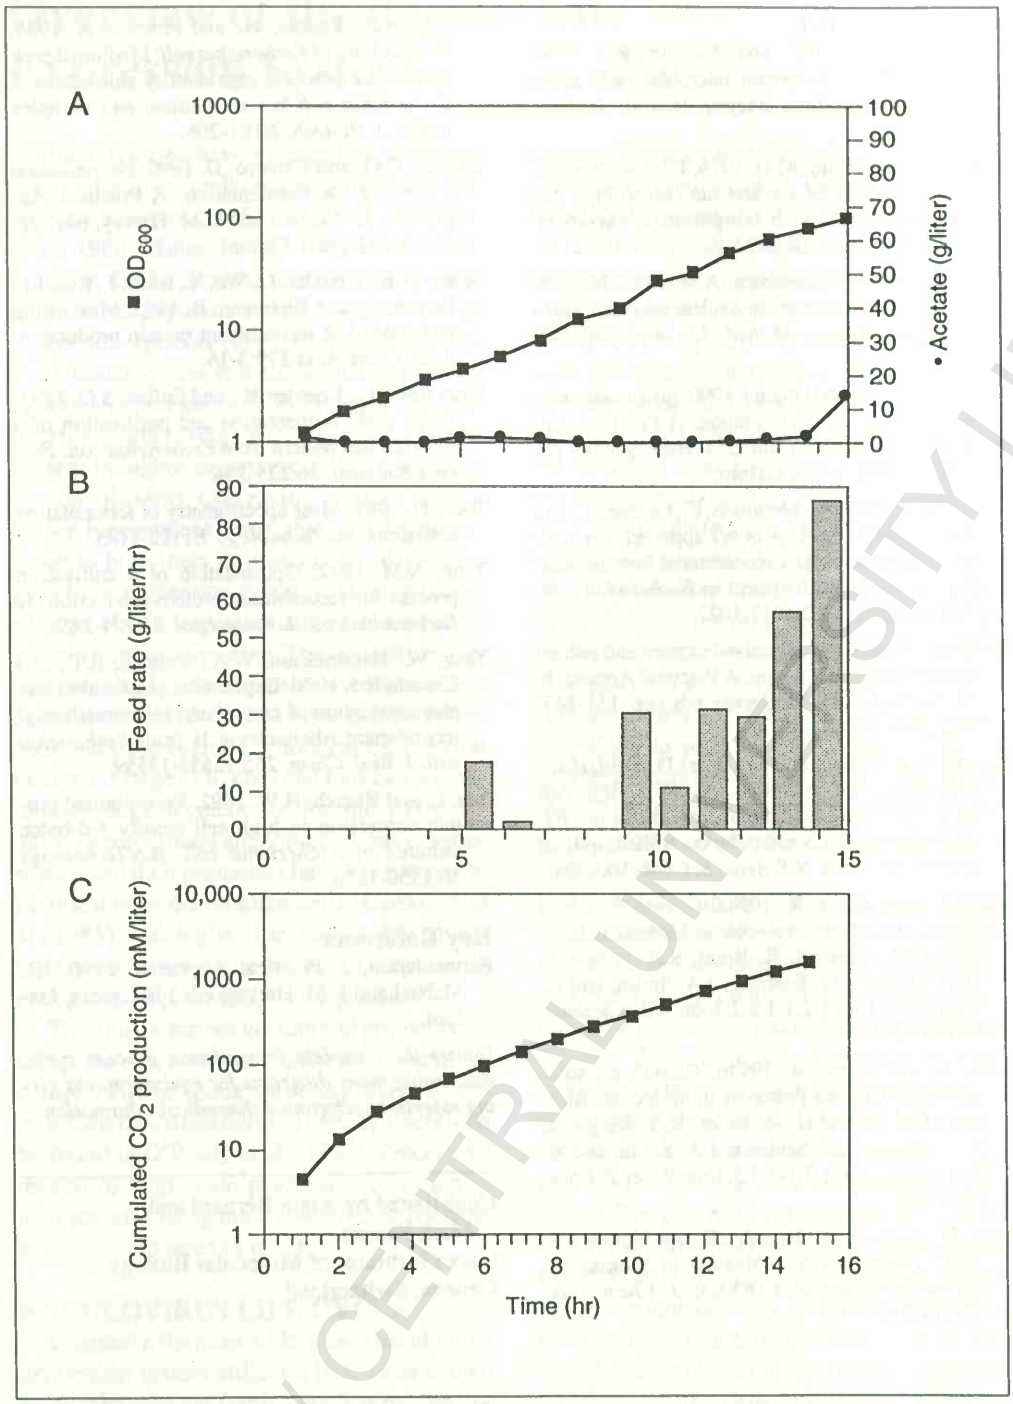

Figure 5.3.3 High-cell-density growth. (**A**) Kinetics of growth (OD_{600}) and acetate production. (**B**) Feed rate profile. Note that the feed rate was adjusted according to growth rate as described in Alternate Protocol 1. (**C**) Kinetics of cumulated CO_2 production. Mass spectrometry of the exhaust gas was performed as described by Todd (1989). Acetate formation was measured as described by Reiling et al. (1985).

Overview of the Baculovirus Expression System

Baculoviruses have emerged as a popular system for overproducing recombinant proteins in eukaryotic cells (Luckow and Summers, 1988; Miller, 1988; Miller et al., 1986; Luckow, 1991). Several factors have contributed to this popularity. First, unlike bacterial expression systems (*UNITS 5.1-5.3*), the baculovirus-based system is a eukaryotic expression system and thus uses many of the protein modification, processing, and transport systems present in higher eukaryotic cells. In addition, the baculovirus expression system uses a helper-independent virus that can be propagated to high titers in insect cells adapted for growth in suspension cultures, making it possible to obtain large amounts of recombinant protein with relative ease. The majority of this overproduced protein remains soluble in insect cells, in contrast to the insoluble proteins often obtained from bacteria. Furthermore, the viral genome is large (130 kbp) and thus can accommodate large segments of foreign DNA. Finally, baculoviruses are noninfectious to vertebrates, and their promoters have been shown to be inactive in mammalian cells (Carbonell et al., 1985), which gives them a possible advantage over other systems when expressing oncogenes or potentially toxic proteins.

This unit describes vectors and protocols for using the baculovirus expression system. A comprehensive guide outlining most of the protocols described here (as well as others) can be found in O'Reilly et al. (1992). Procedures related to large-scale production of recombinant proteins using the baculovirus expression system are covered in *UNIT 5.5*.

BACULOVIRUS LIFE CYCLE

Currently, the most widely used baculovirus expression system utilizes a lytic virus known as *Autographa californica* nuclear polyhedrosis virus (AcMNPV; hereafter called baculovirus). This virus is the prototype of the family *Baculoviridae*. It is a large, enveloped, double-stranded DNA virus that infects arthropods. The baculovirus expression system takes advantage of some unique features of the viral life cycle (Fig. 5.4.1). See Doerfler and Bohm (1986) for a comprehensive review.

As with mammalian DNA viruses, the baculovirus life cycle is divided temporally into immediate early, early, late, and very late phases. Viruses enter the cell by adsorptive endocytosis and move to the nucleus where their DNA is released. DNA replication begins ~6 hr after infection. Replication is followed by viral assembly in the nucleus of the infected cell. Two types of viral progeny are produced during the life cycle of the virus: extracellular virus particles (nonoccluded viruses) during the late phase and polyhedra-derived virus particles (occluded viruses) during the very late phase of infection. Extracellular virus is released from the cell by budding, beginning at ~12 hr postinfection, and is produced at a logarithmic rate until 20 hr postinfection, after which production drops off. Polyhedra-derived virus, on the other hand, appears in the nucleus at ~18 hr postinfection and continues to accumulate as late as 72 hr postinfection, or until the cells lyse. Occluded viral particles are embedded in proteinaceous viral occlusions called polyhedra within the nucleus of infected cells. The polyhedrin protein (29 kDa) is the major protein component of the occlusion bodies.

The polyhedrin protein serves an important function for the survival and propagation of the virus in nature. Because baculoviruses are lytic, they quickly kill their insect host after infection. The polyhedrin protein serves to sequester, and thereby protect, hundreds of virus particles from proteolytic inactivation by the decomposing host tissue. The virus is transmitted when occlusion bodies are ingested by a new host as it feeds on a contaminated food source. The polyhedrin protein dissolves in the alkaline environment of the new host's gut and the occluded virus is released. This virus infects the gut epithelial cells and virus replication takes place. Nonoccluded virus is then produced and budded from the infected gut cells. At this point, the virus spreads throughout the tissues of its new host. Although the polyhedrin protein is essential for survival of the virus in nature, it is dispensable for virus survival and propagation in tissue culture cells.

BACULOVIRUS EXPRESSION SYSTEM

The baculovirus expression system takes advantage of several facts about polyhedrin protein: (1) that it is expressed at very high levels in infected cells, constituting more than

BOSTON UNIVERSITY LIBRARY

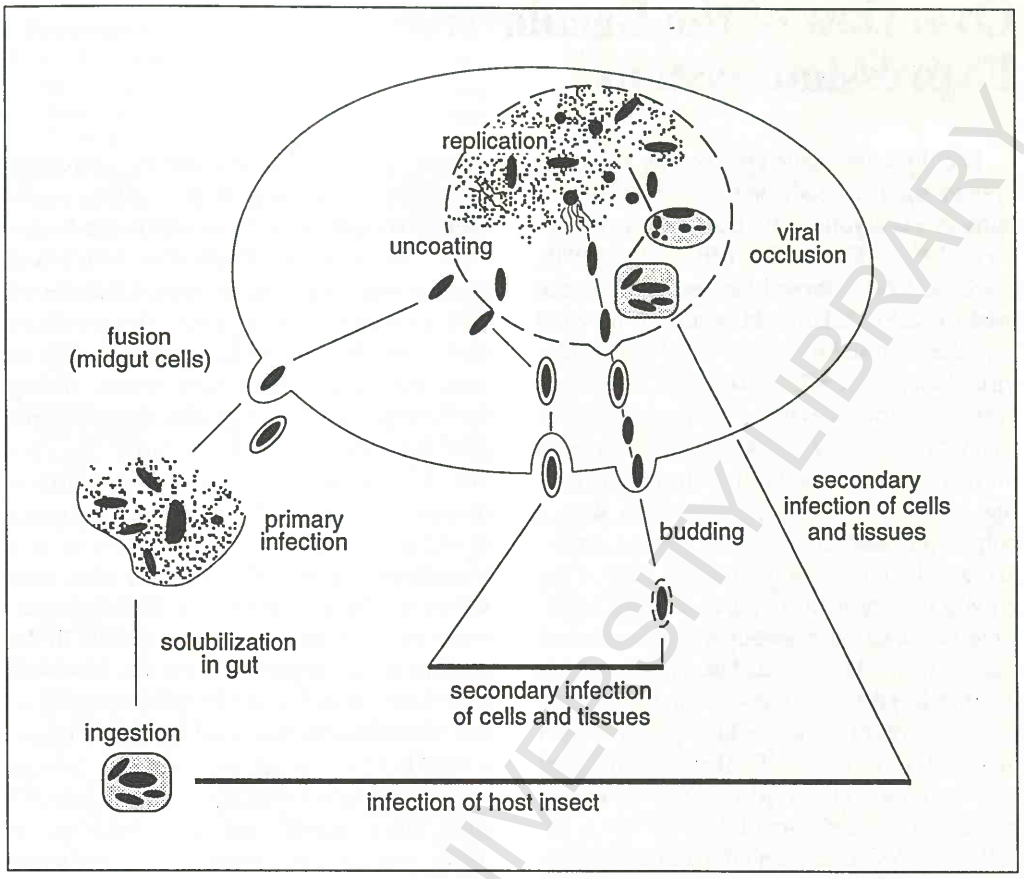

Figure 5.4.1 Baculovirus life cycle. Viruses enter cells by adsorptive endocytosis and move to the nucleus where their DNA is released. Both DNA replication and viral assembly take place in the nuclei of infected cells to generate two types of viral progeny. These include extracellular (non-occluded) virus particles and polyhedra-derived (occluded) virus particles. Extracellular virus is released from the cell by budding, starting at ~12 hr postinfection and ending ~36 hr postinfection. Polyhedra-derived virus appears later (~18 hr postinfection) and accumulates in the nuclei of infected cells ≤72 hr postinfection or until cellular lysis. Polyhedra-derived virus is embedded in proteinaceous viral occlusions, the major protein component of which is the viral polyhedrin protein. Secondary infection of cells and tissues occurs by two pathways. In the first, the extracellular virus, once budded from the site of primary infection, is free to infect neighboring cells by the pathway just described. Alternatively, polyhedra-derived virus is released from occlusion bodies after an infected food source is ingested by a new host. Reproduced from Summers and Smith (1987) with permission from the Texas Agricultural Experiment Station.

half of the total cellular protein late in the infectious cycle; (2) that it is nonessential for infection or replication of the virus, meaning that the recombinant virus does not require any helper function; and (3) that viruses lacking the polyhedrin gene have a plaque morphology which is distinct from that of viruses containing the gene. Recombinant baculoviruses are generated by replacing the polyhedrin gene with a foreign gene through homologous recombination. In this system, the distinctive plaque morphology provides a simple visual screen for identifying the recombinants.

To produce a recombinant virus that expresses the gene of interest, the gene is first cloned into a transfer vector (described below). Most baculovirus transfer vectors contain the polyhedrin promoter followed by one or more restriction enzyme recognition sites for foreign gene insertion. Once cloned into the expression vector, the gene is flanked both 5′ and 3′ by viral-specific sequences. Next, the recombinant vector is transfected along with wild-type viral DNA into insect cells. In a homologous recombination event, the foreign gene is inserted into the viral genome and the polyhedrin gene is excised. Recombinant viruses lack the polyhedrin gene and in its place contain the inserted gene, whose expression is under the control of the polyhedrin promoter.

RCU IASLIC CENTRAL UNIVERSITY LIBRARY

Homologous recombination between circular wild-type DNA and the recombinant plasmid DNA occurs at a low frequency (typically 0.2% to 5%). However, linearization of wild-type baculovirus DNA before cotransfection with plasmid DNA increases the proportion of recombinant virus to ~30% (Kitts et al., 1990). If the DNA is linearized such that an essential portion of the 1629 open reading frame (ORF) downstream from the polyhedrin gene is deleted, 85% to 99% of the viruses obtained by cotransfection with a plasmid vector that complements the deletion express the heterologous gene (Kitts and Possee, 1993). Two companies (Pharmingen and Clontech) market linear AcMNPV DNA containing such a deletion.

Once a virus stock is obtained after cotransfection, it is necessary to purify recombinant virus by plaque assay so the recombinant virus can be identified. Limiting dilution can also be used (see O'Reilly et al., 1992). One of the beauties of this expression system is a visual screen allowing recombinant viruses to be distinguished. As mentioned above, the polyhedrin protein is produced at very high levels in the nuclei of infected cells at late times after viral infection. Accumulated polyhedrin protein forms occlusion bodies that also contain embedded virus particles. These occlusion bodies, up to 15 μm in size, are highly refractile—i.e., they have a bright, shiny appearance that is readily visualized under the light microscope. Cells infected with recombinant viruses lack occlusion bodies. Thus, when the virus is plaqued onto *Sf*9 (*Spodoptera frugiperda*) cells, plaques can be screened for the presence (indicative of wild-type virus) or absence (indicative of recombinant virus) of occlusion bodies. Recombinant viruses can also be identified by DNA hybridization and polymerase chain reaction (PCR) amplification.

POST-TRANSLATIONAL MODIFICATION OF PROTEINS IN INSECT CELLS

Because baculoviruses infect invertebrate cells, it is possible that the processing of proteins produced by them is different from the processing of proteins produced by vertebrate cells. Although this seems to be the case for some post-translational modifications, it is not the case for others. For example, two of the three post-translational modifications of the tyrosine protein kinase, pp60$^{c\text{-}src}$, that occur in higher eukaryotic cells (myristylation of the N-terminal glycine residue and phosphorylation of serine 17) also take place in insect cells. However, another modification of pp60$^{c\text{-}src}$ observed in vertebrate cells, phosphorylation of tyrosine 527, is almost undetectable in insect cells (Piwnica-Worms et al., 1990).

In addition to myristylation, palmitylation has been shown to take place in insect cells. However, it has not been determined whether all or merely a subfraction of the total recombinant protein contains these modifications. Cleavage of signal sequences, removal of hormonal prosequences, and polyprotein cleavages have also been reported, although cleavage varies in its efficiency. Internal proteolytic cleavages at arginine- or lysine-rich sequences have been reported to be highly inefficient, and alpha-amidation, although it does not occur in cell culture, has been reported in larvae and pupae (Hellers et al., 1991). In most of these cases a cell- or species-specific protease may be necessary for cleavage. Protein targeting seems conserved between insect and vertebrate cells. Thus, proteins can be secreted and localized faithfully to either the nucleus, cytoplasm, or plasma membrane. Although much remains to be learned about the nature of protein glycosylation in insect cells, proteins that are N-glycosylated in vertebrate cells will also generally be glycosylated in insect cells. However, with few exceptions the N-linked oligosaccharides in insect cell-derived glycoproteins are only high-mannose type and are not processed to complex-type oligosaccharides containing fucose, galactose, and sialic acid. O-linked glycosylations have been even less well characterized in *Sf*9 cells, but have been shown to occur. For further information on protein processing in insect cells, see Jarvis and Summers (1992) and O'Reilly et al. (1992).

Protein Expression in the Baculovirus System

Insect cell–recombinant baculovirus co-cultures offer a protein production system that complements microbial systems (*UNITS 5.1-5.3*) by providing recombinant proteins in soluble form and with most post-translational modifications. Moreover, the large size of the viral genome (130 kbp) enables cloning of large segments of DNA and consequent expression of complex protein aggregates. This unit describes methods associated with the large-scale production of recombinant proteins in the baculovirus expression system. *UNIT 5.4* gives an overview of this system. Performing the protocols in this unit requires that the desired protein has already been cloned into an appropriate vector for expression in cultured insect cells under the control of a strong baculoviral promoter; it is also assumed that both infection of cells by the recombinant virus and production of recombinant proteins have been analyzed in preliminary experiments. Detailed protocols for the construction of a recombinant baculovirus, maintenance of insect cells in culture, and analysis in small-scale expression experiments can be found in several manuals (Murphy and Piwnica-Worms, 1994a,b; Summers and Smith, 1987).

Production of proteins in large amounts requires correspondingly large quantities of starting materials, most importantly viral stocks of high titer. Basic Protocol 1 gives a method for large-scale production of viral stocks. Quality control is absolutely vital, and methods for titration of virus are provided (Support Protocols 1 and 2 describe the plaque assay and the end-point assay, respectively). Moreover, once viral stocks have been prepared and titered, the virus is tested in small-scale cultures to determine the kinetics of expression (Basic Protocol 2), which allows evaluation of various cell culture and infection conditions aimed at developing optimal levels of protein production (e.g., comparisons of different host cell lines, media, and environmental parameters). Support Protocol 4 provides instructions for preparing culture samples for protein analysis by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE; *UNIT 10.1*), and Support Protocol 5 discusses analytical methods for monitoring nutrient levels in cell culture fluids.

Once optimal process parameters are identified, the target protein can be produced on a large scale in fermentors. Basic Protocol 3 describes regular batch production in bioreactors, whereas Alternate Protocol 1 covers a variant fed-batch procedure of production in perfusion cultures. Techniques for harvesting cultures from bioreactors are provided in Support Protocol 3. These protocols produce cell pellets or culture supernatants containing the protein of interest, which must then be subjected to purification and analysis as described elsewhere in this manual (Chapters 6 and 7).

Despite being based on the use of a virus, the expression of recombinant protein with the baculovirus system is not hazardous to humans, as the virus cannot infect cells of noninsect origin. Nonetheless, handling of virus stocks should be restricted to well-defined equipment, materials, and rooms, kept separate from those where the host cell lines are maintained. This helps prevent any uncontrolled latent viral infection of the host cell line stocks.

NOTE: All protocols (except Support Protocol 4 and Support Protocol 5) should be carried out using strict sterile technique, in the absence of antibiotics.

BASIC PROTOCOL 1

LARGE-SCALE PRODUCTION OF VIRAL STOCK

The first phase of large-scale production of recombinant proteins is the generation of a large volume (1 to 5 liters) of highly infective recombinant virus. A culture of insect cells is prepared, grown to mid-exponential phase, and infected with recombinant virus. On day 4 or 5 postinfection, the culture is harvested by centrifugation and then stored. A small sample of the culture is reserved for titering by the plaque assay or by the end-point dilution method (see Support Protocols 1 and 2). High-titer stocks are used in the analysis of expression kinetics (see Basic Protocol 2) and in the infection of reactor cultures (see Basic Protocol 3 and Alternate Protocol 1).

Materials

Spodoptera frugiperda (*Sf*9) cells
Insect cell medium: TC100 (GIBCO/BRL) or IPL41 (GIBCO/BRL), with 5% to 10% (w/v) fetal calf serum (FCS); or Sf-900 II (GIBCO/BRL), serum free
Pure recombinant virus (at 10^7 pfu/ml)

1-liter to 10-liter capacity shaker flasks or spinner culture flasks
27°C shaker incubators, humidity controlled
Low-speed centrifuge (Sorvall RC3B or equivalent)
1-liter glass conical-bottom centrifuge bottles (Corning or Bellco), sterile

Additional reagents and equipment for monitoring cell growth by cell counting and determining cell viability with trypan blue (see Support Protocol 6), monitoring nutrient levels in culture media (see Support Protocol 5), and titration of virus (see Support Protocols 1 and 2)

1. Prepare a 500-ml culture of *Sf*9 cells in a shaker flask or spinner culture flask containing prewarmed insect cell medium (with or without serum) in a 27°C shaker incubator under controlled humidity.

   Always use a low liquid/total volume ratio (<0.4) to ensure good aeration of the culture while minimizing mechanical shear effects. Pluronic F-68 (BASF) should be included at 2 g/liter in media that lack a shear protectant. Set agitation to 50 to 100 rpm to ensure good mixing and aeration.

   To avoid uncontrolled infection, noninfected cultures should be handled separately and kept physically apart from infected cultures (use different incubators and different microbiological hoods).

   The Sf9 cell line should be maintained and regularly passaged two to three times per week in either monolayer cultures or small shaker cultures in the same medium as the one chosen for the protocol. Maintainance of the cell line is described in Murphy and Piwnica-Worms (1994a).

2. Withdraw a sample of culture and perform appropriate tests to monitor cell growth, viability, and nutrient levels to ensure an adequate growth environment.

   Growth should be monitored by cell counting using a hemocytometer and microscope. The culture should be initiated with a minimum of 2-3 × 10^5 cells/ml, at a viability higher than 98%. Healthy cells of high viability are characterized under the microscope by regular spherical shapes, smooth membranes, and refractile nuclei. Viable cells exclude trypan blue dye, whereas dead cells don't (see Support Protocol 6). Elongated cell shapes or rough cytoplasmic membranes may be an indicator of oxygen limitation (this can be relieved by increased agitation or reduced culture volume/vessel volume ratios). Nutrient levels are measured using an assortment of specific assays (see Support Protocol 5). Typically, glucose and glutamine levels should not decrease below 0.2 g/liter and 0.2 mM, respectively.

3. When the culture reaches mid-exponential phase (~ 1 to 5 × 10^6 cells/ml depending on the cell line and medium employed), infect with an aliquot of the pure recombinant

BCU IASI CENTRAL UNIVERSITY LIBRARY

virus to achieve a low multiplicity of infection (0.01 to 0.1). Transfer the spinner or shaker flask to a biological hood reserved for handling virus-infected cultures. Carefully open the flask and using a sterile pipet, add the appropriate volume of virus suspension to the culture. Mix the contents of the flask by gentle swirling, close the flask, and return it to the incubator.

For a 500-ml culture at 1×10^6 cells/ml, 5 ml of a virus suspension at 10^7 pfu/ml is appropriate.

The multiplicity of infection (MOI) is the ratio of infective virus particles per cell. The volume of virus solution (V_v, in ml) to add to a culture volume (V_c, in ml) is calculated as $V_v = MOI \times N \times V_c/T$, where N is the cell density in the culture (cells/ml) and T is the titer of the virus solution (pfu/ml).

4. Incubate culture 4 to 5 days in a 27°C shaker incubator under controlled humidity to allow virus production. Monitor cell growth once per day.

   At 4 to 5 days postinfection a large proportion of the cells (>50%) display hallmarks of infection: large cell bodies, condensed nuclei, rough membranes, and, for some cell lines, sausage shapes. At this stage, viability should be <20%.

5. Harvest the culture by centrifugation in sterile conical-bottom bottles for 30 min at $200 \times g$, 4°C, to remove cell debris. Retain the supernatant as the viral stock.

   Before discarding cell debris, inactivate all viruses in the pellet by soaking 30 min in 1 N NaOH.

6. Withdraw a small sample (e.g., 5 ml) for viral titration and store remaining stock at 4°C, protected from light, in 175-cm^2 tissue culture flasks.

   Viral stocks can be stored in the dark for several months at 4°C without significant loss of infectivity. Low-titer viral stocks ($<5 \times 10^7$ pfu/ml) may be more unstable, and titration of existing viral stocks should be performed immediately before use. Exposure to light has been shown to reduce virus infectivity during long-term storage (Jarvis et al., 1994).

   Two to three aliquots of 1 ml each can be dispensed in sterile cryovials under the biological hood (see UNIT 5.2, Support Protocol 3), tightly closed, and stored in liquid nitrogen as a back-up source for the virus. Freezing of the virus suspension, however, may lead to loss of virus titer. This loss, combined with the small volume that is frozen, would not eliminate the need to go back to step 1 of this protocol to generate a high-titer virus stock.

7. Estimate the titer of the reserved stock sample either by the plaque assay or by the end-point dilution method (see Support Protocols 1 and 2).

   Stocks of $<10^7$ pfu/ml are useless and should be discarded. $1\text{-}5 \times 10^7$ pfu/ml are considered to be low titer. The expected average titer is 10^8 pfu/ml.

DETERMINATION OF EXPRESSION KINETICS

BASIC PROTOCOL 2

Once a viral stock is made with a titer above 5×10^7 pfu/ml, the kinetics and the level of protein expression are characterized in small-scale cultures in terms of the optimal cell culture and infection parameters. The following protocol can be used to compare host cell lines, media, virus constructs, and usual process parameters (e.g., cell density, pH, and agitation). It involves growing small-volume cultures of insect cells, infecting with virus stock, and periodically withdrawing culture samples that are prepared for protein analysis (see Support Protocol 4). The results are used to guide the timing of harvesting in large-scale production systems (see Basic Protocol 3 and Alternate Protocol 1).

BCM LABS / CENTRAL UNIVERSITY LIBRARY

Materials

Cell line: *Spodoptera frugiperda* (*Sf*9, *Sf*21; ATCC, Pharminogen, Invitrogen) *or Trichoplusia ni* (*Tn*5 line; High Five cell line, Invitrogen)
Insect cell medium: TC100 (GIBCO/BRL) or IPL41 (GIBCO/BRL), serum free or with 5% to 10% (w/v) fetal calf serum (FCS); or Ex-Cell 401 or Ex-Cell 405 (JRH Biosciences) or Sf-900 II (GIBCO/BRL), serum free
Recombinant viral stock (see Basic Protocol 1)

1.5- to 3-liter shaker flasks or spinner culture flasks
27°C incubator, humidity controlled

Additional reagents and equipment for monitoring cell growth by cell counting and determining cell viability with trypan blue (see Support Protocol 6), monitoring nutrient levels in culture media (see Support Protocol 5), and preparing samples for protein analysis (see Support Protocol 4)

1. Prepare a culture of cells in a 1.5- to 3-liter shaker flask or spinner culture flask containing 0.5 to 1 liter insect cell medium (with or without serum). Place flask in a 27°C incubator and allow cells to grow. Monitor cell growth, cell viability, and nutrient levels.

   Growth should be monitored by cell counting using a hemacytometer and microscope, and cell viability is determined by the trypan blue exclusion method (see Support Protocol 6). Nutrient levels are measured using an assortment of specific assays (see Support Protocol 5).

   In serum-containing media, the cell density should not exceed 1×10^6 cells/ml at time of infection. In serum-free media, infection can be started at up to 5×10^6 cells/ml. Prepare separate test cultures for each cell culture and infection variable to be analyzed (e.g., MOI, cell line, medium, and cell density).

2. Infect culture at high MOI (5 to 10) by sterile addition of an aliquot of recombinant viral stock. Return culture to 27°C incubator and incubate under controlled humidity.

   To calculate the amount of virus stock to add, use the calculations given in Basic Protocol 1, step 3. For example, for a 500-ml culture at 10^6 cells/ml, adding 5 ml of a virus stock (at 10^8 pfu/ml) would give an MOI of 1; 50 ml of the same stock would result in an MOI of 50.

   In some cases, it may be advantageous to centrifuge the cells and suspend them in fresh medium just prior to infection. This avoids possible nutrient limitation and toxic by-product inhibition during infection.

3. Withdraw 10-ml culture samples, measure nutrient levels (see Support Protocol 5), and prepare aliquots for protein analysis (see Support Protocol 4). Monitor nutrient levels and cell viability using trypan blue on a regular basis (twice per day) until 4 to 5 days postinfection.

   Once infected, cells are not necessarily completely permeable to trypan blue, and intermediate levels of staining can be observed. Also, some cell lines still exclude trypan blue quite effectively even when fully infected. An increase in cell size is usually a better indicator of infection.

4. Determine the optimal harvest time from the kinetics of target protein expression.

   SDS-PAGE (UNIT 10.1), immunoblotting, and biological assay, if available; may be used to analyze protein levels. For some proteins, it may be beneficial to harvest before the actual peak of expression because of progressive proteolytic degradation. Such degradation may be apparent as undersized immunoreactive bands in blots.

   Because the infection has been carried well beyond the optimal harvesting time, and unless the desired protein is expressed at very high levels and is very stable, the test cultures cannot be used further. They should be neutralized for 30 min in 1 N NaOH.

ECU IASI / CENTRAL UNIVERSITY LIBRARY

PRODUCTION IN BIOREACTORS

This protocol describes large-scale production of recombinant proteins in insect cell cultures conducted in bioreactors. Equipment preparation involves inspecting the reactor for cleanliness, calibrating sensors, and sterilizing. Culture medium is introduced through a sterilizing filter and then inoculated with exponentially growing, uninfected insect cells prepared in shaker or spinner flasks (see Basic Protocol 1, steps 1 and 2). Once cells reach half-maximal density, viral stock is introduced. The culture is terminated at the appropriate time, as determined in small-scale experiments (see Basic Protocol 2), and harvested (see Support Protocol 3). Because cultures are performed for days or weeks in the absence of antibiotics, maintaining the sterility of all operations is essential. This method may be adapted to perfusion cultures (see Alternate Protocol 1).

Materials

Insect cell medium: TC100 (GIBCO/BRL) or IPL41 (GIBCO/BRL), serum free or with 5% to 10% (w/v) fetal calf serum (FCS); or Ex-Cell 401 (JRH Biosciences) or Sf-900 II (GIBCO/BRL), serum free

Inoculum (15% to 20% bioreactor culture volume): spinner or shaker flask culture of uninfected insect cells and in full exponential growth phase

Recombinant viral stock (see Basic Protocol 1)

Bioreactor fitted with temperature, pH, agitation, air flow, and pO_2 control (see Table 5.3.1 and Fig. 5.3.1)

Millipak filter, sterile (Millipore)

Viral stock and inoculum transfer vessel fitted with transfer line (see Fig. 5.3.2)

Peristaltic pump (optional)

Additional reagents and equipment for checking sterility and monitoring cell growth and determining cell viability with trypan blue (see Support Protocol 6)

1. Prepare bioreactor by inspecting for the absence of residual biological material on the reactor vessel walls, agitator shaft baffles, or other parts; calibrating sensors for temperature, pH, pO_2 and pressure; and sterilizing accessory lines and transfer vessels by autoclaving. Fill reactor vessel with water such that all probe tips are immersed and sterilize. Empty reactor.

   If the bioreactor is autoclaved, it is important to ensure proper monitoring of the temperature inside the reactor (UNIT 5.3).

2. Connect medium addition line and add medium through a sterilizing filter. Disconnect medium addition line.

   The volume of the medium added is 75% to 80% of the final culture volume desired. This allows for cell inoculum and viral stock additions.

3. Set all parameters to the respective set points.

   Among strategies available to control dissolved oxygen levels in the culture (e.g., flow rate of gas, agitation, control through headspace), pure O_2 pulsing through the sparger is the easiest method to monitor. A permanent airflow through the reactor headspace (at 1 liter air/liter culture/min) also damps possible oscillations around the set point. Generally, a set point of 30% to 50% air saturation should be optimal.

   If possible, leave the bioreactor in an uninoculated state for 24 to 48 hr. Check sterility to detect contaminants and to avoid loss of valuable inoculum.

4. Inoculate bioreactor with inoculum consisting of a spinner or shaker flask culture of uninfected insect cells at high viability and in full exponential growth phase so as to obtain a starting density of 2 to 3×10^5 cells/ml. Pool cultures if necessary and transfer

BOJAS / CENTRAL UNIVERSITY LIBRARY

into a sterile inoculation transfer vessel under a biological hood. Connect transfer vessel as described in *UNIT 5.3*.

Use a septum port that has not been previously used for emptying or filling the reactor.

The growth characteristics of the inoculum should have exhibited predictable and reproducible growth rates during previous subculture.

5. Transfer the inoculum aseptically into the reactor either via a peristaltic pump or by pressurizing the inoculum vessel with sterile air.

   Foaming of the culture should be avoided at all times during the transfer.

6. Monitor cell growth until cell density reaches half-maximal levels, as estimated from inoculum growth curves.

7. Infect culture at high MOI (5 to 10) by aseptically adding recombinant viral stock as described for inoculum addition in step 5. Allow virus infection, virus replication and protein expression to proceed for 4 to 5 days, withdrawing samples twice daily and determining cell viability and nutrient levels (see Support Protocol 5). In addition, prepare aliquots of the sample twice daily for protein analysis (see Support Protocol 4). Terminate the process by harvesting at the optimal time point (see Basic Protocol 2 regarding determination of this time point).

   The multiplicity of infection (MOI) is the ratio of infective virus particles per cell. The volume of virus solution (V_v in ml) to add to a culture volume (V_c in ml) is calculated as $V_v = MOI \times N \times V_c/T$, where N is the cell density in the culture (cells/ml) and T is the titer of the virus solution (pfu/ml).

8. Harvest by centrifugation or tangential flow microfiltration (see Support Protocol 3).

   Depending on the target protein localization, keep the cell pellet or the supernatant fraction. Representative samples should be collected before and after any of the following downstream processes (see Support Protocol 3 and Support Protocol 4) to monitor changes in target protein stability or conformation.

ALTERNATE PROTOCOL 1

PRODUCTION IN PERFUSION CULTURES

Perfusion cultures permit high cell densities and production of greater protein amounts than simple batch methods (see Basic Protocol 3), particularly if proteins are designed for secretion. Equipment setup is as in Basic Protocol 3 except that a tank containing extra medium is set on a load cell and connected to the reactor, and a cell retention device is included along with a holding tank for spent medium. After the reactor is inoculated with insect cells, fresh medium is added to the culture at increasing rates to match the increase in cell density. Spent medium (free of cells) is withdrawn at the same rate to keep reactor volume constant. Because of the large holding tanks required, this protocol can be easily implemented at reactor scales of 1 to 5 liters but requires an industrial production environment for larger scales.

Additional Materials (also see Basic Protocol 3)

Cell retention device: spin filter, internal membrane filter, external membrane filter, or external centrifuge
Fermentor level controller (contact probe)
Medium feed and filtrate polypropylene holding tanks (10 to 15 times reactor volume; Nalgene)
Load cell or electronic balance for feed tank (Mettler or equivalent)
Peristaltic pumps (Watston-Marlow or equivalent)
Additional reagents and equipment for determining cell viability with trypan blue

BCU IASL CENTRAL UNIVERSITY LIBRARY

(see Support Protocol 6), and preparing samples for protein analysis (see Support Protocol 4)

1. Prepare the bioreactor and start the culture (see Basic Protocol 3, steps 1 to 6). Be sure to equip the bioreactor with a cell retention device and a fermentor level controller.

   Set up the level controller so that it activates addition of fresh medium to the reactor by a peristaltic pump as culture volume decreases.

   The decrease in culture volume is caused by continuous withdrawal of cell-free filtrate by another pump. The speed of this second pump determines the perfusion rate (0.5 to 4 culture volumes/day).

   The equipment used here is available from most fermentor manufacturers and can be adapted to standard batch-oriented designs (see Table 5.3.1). For a thorough review of perfusion hardware, see Tokashiki and Takamatsu (1993).

2. Prepare a large volume of medium in a feed tank. Set tank on load cell or electronic balance.

   Feed and filtrate holding tanks should be of at least 10× the reactor capacity. This explains why it is more difficult to run large reactors (more than 5 to 6 liters) in perfusion in a common laboratory environment.

3. Connect feed tank to the reactor and connect filtrate holding tank to the filtrate port of the cell retention device. Set up peristaltic pumps for medium feed and filtrate removal.

4. Monitor cell growth, and, once cell density has reached half the maximal density for a batch operation, start perfusion with insect cell medium at a rate of 0.5 reactor volume/day.

   Monitor feed rates by recording changes in the weight of the feed tank per unit time (be sure to take into account the density of the feed medium).

5. Gradually increase perfusion rate in proportion to the increase in cell density. Allow 3 to 5 days of perfusion to reach the target cell density.

   The target cell density for infection is 1 to 3×10^7 cells/ml at more than 95% viability.

   Ideally, a perfusion process should be run without infection first to determine the maximal cell density achievable with a given set of hardware, cell line, and medium. However, most reports available in the literature seem to agree with a maximal cell density of 5-6 $\times 10^7$ cells/ml.

6. Infect the culture by adding recombinant viral stock to the reactor (see Basic Protocol 3). Withdraw a 5-ml sample for analysis of protein expression. Halt perfusion for a short time after infection (1 to 2 hr) to allow virus attachment and/or penetration inside the cells.

   This sample will serve as a negative control in protein expression analysis (see Support Protocol 4).

   In this process, because the cell density is unusually high, it may be difficult to achieve a high MOI. However, it has been shown that infection at very low MOI (0.01) is still as productive as a batch operation with a high MOI.

   Perfusion is temporarily halted to prevent virus escape through the cell retention device. To avoid nutrient limitation during the arrest of perfusion, the feed rate can be increased 2- to 3-fold during the hour preceding the infection. Halting perfusion can simply be done by turning off the filtrate withdrawal pump. The rest of the cell retention hardware (filters, pump, centrifuge) should be left running without interruption to avoid any heterogeneity of the whole system.

BOKU WIEN / ZENTRALE UNIVERSITÄTS BIBLIOTHEK

7. Set perfusion rate to maximum (3 to 4 reactor volumes/day).
8. Let infection proceed for at least 4 days. Monitor cell viability and protein expression.
9. To avoid dilution of the product in the filtrate (and if the protein is secreted), remove the accumulated filtrate every 24 hr and concentrate by ultrafiltration (see Support Protocol 3). Prepare sample for analysis (see Support Protocol 4).

If expression of the secreted protein is under control of a late promoter, the accumulated filtrate for the first 24 hr postinfection usually contains little product and can be discarded.

SUPPORT PROTOCOL 1

TITRATING VIRAL STOCKS WITH THE PLAQUE ASSAY

It is important to know the titer of a viral stock when preparing new stocks or when infecting insect cells to produce recombinant proteins. Two methods are used to determine viral titers in stock preparations, namely, the plaque assay and the end-point titration assay (see Support Protocol 2). Both methods are biological assays employing cell culture and quantify only the extracellular infectious forms of baculovirus. The plaque assay involves infecting exponentially growing *Sf*9 cell monolayers with serial dilutions of viral stock (see Basic Protocol 1). After removing the viral supernatant following a period of viral adsorption, an agarose overlay is added and culture is continued for 5 to 7 days before plaques are counted in the culture treated with the highest dilution of virus that elicits an infection.

Materials

*Sf*9 cells (30 ml, 8×10^5 cells/ml)
TC100 medium (GIBCO/BRL), with and without 5% (w/v) fetal calf serum (FCS)
Test sample: viral stock or culture supernatant
3% (w/v) low gelling/melting temperature agarose, autoclaved
2× TC100 medium/10% (w/v) FCS
0.3% (w/v) neutral red, diluted 1:20 in 1× phosphate-buffered saline (PBS, *APPENDIX 2E*; filter sterilize and store in the dark)

6-well cluster dishes, sterile
Pipet tips, sterile
Tubes, sterile
Humid box

1. Seed three sterile 6-well cluster dishes by placing 1.5 ml of exponentially growing (8×10^5 cell/ml) *Sf*9 cells in TC100 medium containing 5% FCS in each well. Place dishes in incubator at 27°C.
2. After monolayer formation (after 30 min to 1 hr incubation), wash cells with TC100 medium (no serum).

Serum-free medium facilitates the adsorption of the virus to the cells.

3. Using sterile pipet tips and tubes, dilute test sample to 10^{-6}, 10^{-7}, and 10^{-8} in serum-free (TC100 medium). Add 300 µl of each dilution to each well of the host cell monolayers. Six repeats of one dilution per plate should be performed. Hold the pipet tip against the wall of the well while dispensing and carefully tilt the plate by hand to ensure an even distribution of the inoculum. Make six replicates of each dilution per plate.
4. Return plates to incubator and let the inoculum virus adsorb 2 hr at 27°C. During incubation, prepare the agarose overlay by melting autoclaved 3% low gelling/melt-

BCU IASI CONTRACT UNIVERSITY LIBRARY

ing temperature agarose in a microwave, cooling to 37°C, and mixing 1:1 with 2× TC100 medium/10% FCS at 37°C.

5. Remove the virus by vacuum pipetting.

   Again, hold the pipet tip against the wall of the well, plate tilted.

6. Rapidly cover with 2 ml agarose overlay per well, and let the agarose harden for 3 to 4 hr at 27°C. Overlay with 1 ml TC100 medium/5% FCS.

   The agarose prevents diffusion of virus released from infected cells over the course of the assay. Thus, only cells immediately adjacent to the cell of primary infection are subsequently infected by progeny virus. When enough cells in the immediate vicinity of the primary infection are lysed, a plaque (or hole in the cell monolayer) results.

7. Incubate plates 5 to 7 days in a humid box in the 27°C incubator.

8. Stain plates for 2 hr with 0.3% neutral red. Invert the plate on absorbent paper to decant excess liquid and store 5 hr in the dark at room temperature to allow plaques to become visible. Count plaques and calculate average of all wells showing clear, separate plaques. Express titers as pfu/ml original test sample.

   Staining of cells is not essential but facilitates plaque observation. Uninfected cells stain red, and areas of cell lysis remain clear due to plaque formation.

TITRATING VIRAL STOCKS WITH THE END-POINT ASSAY

SUPPORT PROTOCOL 2

Titrating virus by the end-point assay is similar to the plaque assay (see Support Protocol 1), but here a single virus can replicate and spread throughout the culture well and ultimately infect all cells present in the well, leading to the cytopathic effect. The titer is first given in $TCID_{50}$ units/ml, which can be transformed to an approximate result in pfu/ml. Infection of cells is assayed by detecting either the recombinant protein or the cytopathic effect.

Materials

*Sf*9 cells (1×10^6 cells/ml), grown in Sf-900 II medium (GIBCO/BRL)
Test sample: viral stock or culture supernatant
Chromogenic substrate for detecting recombinant protein (optional, if available; e.g., Xgal for β-galactose)

96-well microtiter plate, sterile
Multitip pipettor
Pipet tips, sterile
Humid box

1. Add 225 µl exponentially growing *Sf*9 cells (1×10^6 cells/ml, in Sf-900 II medium) to every well of a sterile 96-well microtiter plate.

   Do not allow the plates to stand.

2. Immediately add 25-µl undiluted test sample of virus to the first well.

   Make three replicate dilutions of each sample.

3. Make 10-fold serial dilutions across the plate, directly into the insect cell suspensions, using a multitip pipettor and changing pipet tips between each dilution to prevent carryover of virus on the outside of the tip to the low dilutions.

   Alternatively, dilutions can be made in sterile 1.5-ml microcentrifuge tubes.

B. C. U. „M. [illegible] IAŞI
C H [illegible]

BCU IASI CENTRAL UNIVERSITY LIBRARY

4. Transfer 10 µl of each of the 10^{-6} to 10^{-8} dilutions to a microtiter plate.

   Up to 60 replica wells per dilution can be made.

5. Incubate microtiter plates in a humid box 6 days at 27°C.

   It is important that no evaporation be allowed to occur due to the small volume in each well. Wrapping parafilm around the plate also avoids desiccation.

6. If available, add chromogenic substrate for detecting recombinant protein. Score wells such that evidence of viral infection is taken as a positive result.

   Evidence of viral infection may be simple in the case of virus coding for recombinant protein that can be easily detected (e.g., via the use of chromogenic substrates). Otherwise a positive well is scored on the basis of the presence of the cytopathic effect.

7. Count the number of positive (infected) and negative (uninfected) wells and calculate the theoretical dilution that would yield 50% positives, following the method described in Summers and Smith (1987). To convert $TCID_{50}$ into pfu, multiply by ln(2) (i.e., 0.69).

SUPPORT PROTOCOL 3

HARVESTING

Harvesting of cell cultures can be done by centrifugation or tangential flow microfiltration to separate cell bodies from culture medium. Centrifugation can be done in a batch mode by dividing the material into large centrifuge bottles and processing conventionally. Continuous feed centrifugation requires a continuous feed centrifuge and is effective for volumes of 5 to 20 liters. Larger volumes must be harvested by tangential flow microfiltration, which provides a retentate that must then be transferred to centrifuge bottles and subjected to batch centrifugation. Depending on the target protein localization, either the cell pellet or the supernatant fraction is kept for further purification. Protease inhibitors should be added in all cases and temperature should be kept at ~4°C to limit possible degradation. In practice, however, it becomes expensive to add them before the material is concentrated to a small volume.

Materials

Protease inhibitor mix (see recipe)
1-liter conical-bottom centrifuge bottles (Bellco), sterile
Low-speed centrifuge (Sorvall RC3B or equivalent), continuous feed centrifuge (Heareus Contifuge or equivalent), *or* tangential flow microfiltration system (Microgon KrosFloII or equivalent; 0.04 m^2/liter culture)

To harvest by batch centrifugation (≤5 liters)

1a. Transfer the reactor contents into 1-liter conical-bottom glass centrifugation bottles by pressurizing the headspace into the bottles.

2a. Centrifuge 30 min at 200 × *g*. Concentrate the cell-free supernatant by tangential flow ultrafiltration.

To harvest by continuous feed centrifugation (5 to 20 liters):

1b. Connect the inlet line of the centrifuge to the reactor harvest valve, then connect the filtrate outlet line from the centrifuge to a harvesting tank.

2b. Start centrifuge at 200 × *g*, 250 ml/min. Check that supernatant is clear and free of cells. Concentrate the cell-free supernatant by tangential flow ultrafiltration.

ICU IASI CENTRAL UNIVERSITY LIBRARY

To harvest by tangential flow microfiltration (>20 liters)

1c. Connect the inlet of the filtration system to the reactor harvest valve. Connect the retentate line to a return port at the bottom of the reactor.

It is important that the return port is immersed in the culture to avoid foaming. Alternatively, the reactor contents can be transferred to a harvesting tank, then filtered as described.

2c. Start the circulation pump with the filtrate line closed. Operate without filtration for 3 to 5 min, then open the filtrate line. When the reactor is almost empty, transfer the retentate to centrifuge bottles and centrifuge as described in step 2a. Concentrate the cell-free supernatant by tangential flow ultrafiltration.

The circulation rate and transmembrane pressure should be set so that the average shear rate is <2500 sec^{-1}, and transmembrane pressure should not exceed 500 mbar to obtain optimal filtration and avoid membrane clogging (Maiorella et al., 1991).

PREPARING SAMPLES FOR PROTEIN ANALYSIS

SUPPORT PROTOCOL 4

The preparation of samples for protein analysis depends on the protein that is expressed. For a cell-associated protein, a simple lysis in a detergent-containing buffer usually releases most intracellular and membrane proteins. Alternatively, direct resuspension in the SDS sample buffer also solubilizes all proteins. For a secreted protein, dilute the culture supernatant (after concentration if necessary) with an equal volume of sample buffer. Once prepared by this protocol, samples can be loaded directly onto polyacrylamide gels (*UNIT 10.1*).

Materials

Test sample
SDS sample buffer (*UNIT 10.1*) or detergent lysis buffer (see recipe)
Low-speed centrifuge

1. Pellet cells 5 min at 300 × *g*, 4°C.
2. Suspend in SDS sample buffer or lysis buffer (50 to 100 µl per 10^6 cells).

If the cell pellet is resuspended in lysis buffer, an aliquot of the lysate should then be diluted 1:1 with sample buffer.

3. Store at –20°C or –80°C until analyzed.

Samples can be loaded on SDS-PAGE gels (UNIT 10.1) and analyzed by direct detection (e.g., by Coomassie blue or silver staining; UNIT 10.5) of a band at the expected molecular weight with maximum intensity at optimal harvest time, or by immunodetection after blotting the gel on a membrane (UNIT 10.7). It is good practice to include negative controls (e.g., time 0 of infection, cultures infected with wild-type virus, or noninfected culture samples) as well as positive controls (e.g., partially purified recombinant or natural protein when available, or samples from other expression experiments).

BCU IASTE CENTRAL UNIVERSITY LIBRARY

SUPPORT PROTOCOL 5

MONITORING NUTRIENT LEVELS IN CULTURE MEDIA

Expression of recombinant proteins by cultured cells depends directly on levels of nutrients supplied by the culture medium. This protocol describes analytical techniques for glucose, lactate, glutamine, and ammonia. Monitoring nutrient levels is not an absolute requirement for successful exploitation of the baculovirus expression technology. It is useful, however, for troubleshooting in cases of problems with cell growth, virus stock amplification, and protein production. It allows quality control checks of media and cultures and points to eventual nutrient limitations (glucose, glutamine, and other amino acids) or inhibitory product accumulation (lactate, ammonia). A more exhaustive compendium of biochemical analytical techniques for cell culture can be found in Doyle et al., 1994.

The test sample of 5 to 10 ml is withdrawn from the culture (see Basic Protocols 1 and 2), the cells removed by brief centrifugation or filtration, and the culture fluid subjected to analysis.

Glucose and lactate. Glucose can be analyzed in an automated enzyme assay (Yellow Spring Instruments). Glucose oxidase, immobilized on a membrane, oxidizes glucose in the sample to Glucono-δ-lactone, producing H_2O_2. A platinum electrode, held at an anodic potential, in turn oxidizes H_2O_2 to produce electrons. The electron flow is measured and is directly proportional to the H_2O_2 and therefore also proportional to the glucose concentration. The same machine can analyze lactate on the same sample. Another similar membrane electrode with immobilized L-lactate oxidase at its surface gives a parallel amperometric signal proportional to the lactate concentration in the sample.

Glutamine. Glutamine is a critical nutrient for insect cell metabolism. Because glutamine degrades in liquid media, it is wise to check whether it becomes limiting for growth. Glutamine can be measured by high-performance liquid chromatography (HPLC) or by an enzyme assay in which it is first converted to glutamate and ammonia by glutaminase (Ozturk et al., 1989).

Ammonia. Ammonia can be measured by an enzymatic assay kit (Sigma) or by an ion-specific electrode (Orion 9512BN). For analysis with the ammonia electrode, the solution to be analyzed is first made alkaline by the addition of an equal volume of 0.2 N NaOH. Ammonia gas is generated which diffuses through the semipermeable membrane of the electrode and leads to a voltage potential difference. The assay is linear from 0.2 to 12 mM ammonia (log scale; Ozturk et al., 1989).

SUPPORT PROTOCOL 6

DETERMINATION OF CELL GROWTH AND VIABILITY

This protocol describes growth monitoring by cell counts and viability estimation by the trypan blue exclusion method. The culture sample is first stained with trypan blue, and an aliquot is applied to the chamber of a hemocytometer and examined under an inverted microscope. At least 200 cells should be counted to guarantee accuracy.

Materials

Fresh cell culture sample
0.2% (w/v) trypan blue solution (Sigma)
Ethanol

Hemacytometer
Inverted microscope (×10 objective, phase contrast)

1. Mix 100 µl of the fresh cell culture sample with 100 µl trypan blue solution.

ECU IASH CENTRAL UNIVERSITY LIBRARY

2. Clean the hemocytometer plate and coverslip with ethanol. Dry and fix the coverslip.
3. Fill the hemocytometer chamber with the stained sample.
4. Examine under the inverted microscope and count live (bright) and dead (blue) cells on at least two areas of 25 small squares. Average each count (live and dead) and multiply by 2×10^4 to obtain cell density/ml.

   If there are too many cells to count, dilute the original sample by 5- or 10-fold in PBS and start at step 1 again, taking dilution factor into account for the final result.

5. Calculate viability by the proportion of live cells in the total number (live + dead).

   Healthy, noninfected suspension cultures should give a viability above 95% at all times.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Detergent lysis buffer

1% (v/v) Nonidet P-40 (NP-40)
150 mM NaCl (*APPENDIX 2E*)
50 mM Tris·Cl, pH 8.0 (*APPENDIX 2E*)

Protease inhibitor mix

1 mM phenylmethylsulfonyl fluoride (PMSF)
5 mM iodoacetamide
0.2 mM *Nα-p*-tosyl-L-lysine chloromethyl ketone (TLCK; prepared fresh)
2 mM benzamidine·HCl

CAUTION: *Prepare stock solutions in a chemical fume hood.*

COMMENTARY

Background Information

The baculovirus expression system has become a popular technology to produce recombinant proteins. It is based on the infection of cultured insect cells by a recombinant virus vector in which foreign DNA is integrated under control of the strong viral promoter for polyhedrin protein (*polh*; *UNIT 5.4*). It is used for obtaining recombinant proteins for various purposes; such as biochemical studies, analysis of structure-function relationships, in vivo animal studies, and structural studies.

The system recognizes vertebrate protein targeting signals and thus allows expression of different classes of proteins: cytoplasmic, nuclear, membrane-spanning, and secreted. The host insect cell performs most post-translational modifications, including phosphorylation, acylation, glycosylation, precursor processing, subunit assembly, secretion, and nuclear translocation. The glycosylation patterns reported in the recombinant proteins, however, have been restricted to the high-mannose type in almost all cases. The baculovirus expression system is also extensively used for the construction of complex biological aggregates (e.g., ion channels, viral capsids, and multisubunit enzymes). It is biologically safe. Instructions for constructing recombinant baculovirus and small-scale expression experiments are available in other manuals (Murphy and Piwnica-Worms, 1994a,b; Summers and Smith, 1987).

The *polh* promoter is the most widely used promoter to date and many of the available transfer vectors use it. However, p10, another very late, very strong promoter is also being used (McCutchen et al., 1991; Stewart et al, 1991; Belyaev and Roy, 1993; Wang et al., 1993; Bonning et al., 1994; Deramoudt et al., 1994; van-Lier et al., 1994). In addition, the use of earlier promoters (e.g., basic protein promoter, also called *pCor*) is also exploited. With this promoter, expression of the recombinant protein starts at about 20 hr postinfection and peaks at 30 to 36 hr postinfection (Sridhar and Hasnain, 1993; Sridhar et al., 1993; Rankl et al., 1994; Chazenbalk and Rapoport, 1995). At these times, the host functions involved in protein processing are much less affected by viral infection.

BOULDER LIBRARY UNIVERSITY

Before large-scale production of recombinant proteins with the baculovirus system can be undertaken, it is necessary to prepare large-volume stocks of recombinant virus (see Basic Protocol 1). The stocks must have a known titer (see Support Protocols 1 and 2) and must be analyzed in small-scale cultures (see Basic Protocol 2) to determine optimal process parameters. Analysis includes preparing samples for electrophoresis (see Support Protocol 4) and monitoring nutrient levels in culture media (see Support Protocol 5). The results of analysis of the kinetics of recombinant protein expression are used to determine the optimal harvest time, which is a balance between maximal production and minimal degradation.

Once optimal process parameters (e.g., cell line, media, MOI, time of harvest) are identified, the target protein can be produced on a large scale in bioreactors (see Basic Protocol 3). The design of an animal cell bioreactor is similar to that of a microbial fermentor (Fig. 5.3.1) with modifications of the agitation (e.g., lower range of motor speeds, 20 to 200 rpm; marine impeller instead of Rushton turbine) and aeration (lower range of gas flow rates, headspace aeration) systems (for a review, see Hu and Wang, 1986). Equipment preparation is identical to that of a microbial reactor (*UNIT 5.3*), and harvesting is by batch centrifugation, continuous feed centrifugation, or tangential flow microfiltration (see Support Protocol 3). Because cell culture processes are run for days or weeks, without any antibiotics, special attention should be paid to the sterility of all operations.

Perfusion of insect cell cultures (see Alternate Protocol 1) is an effective technique to increase cell density and volumetric productivity of a reactor. It is particularly well suited to processes for the production of secreted proteins. The basis of the technique is to retain the cells inside the reactor by an internal spin filter, an external filter, or an external centrifuge (for a review, see Tokashiki and Takamatsu, 1993) while adding fresh medium and withdrawing spent medium at equal rates to maintain a constant reactor volume.

Critical Parameters and Troubleshooting

Insect cell line. Recombinant product expression levels are cell line–dependent (Hink et al., 1991), and it may therefore be advantageous to screen a number of cell lines for relative productive capacities. The robustness, ease of handling in suspension and in large-scale reactors, and nutrient requirements are also key parameters to consider when choosing a production cell line. Generally, *Sf*9 cells (*Spodoptera frugiperda* clone 9, derived from fall armyworm ovaries) are superior for production of virus, whereas Tn5 cells are superior for secreted proteins. From a practical point of view, it is possible to generate virus stocks in one cell line to be used for recombinant protein production in another.

Maintenance of cell lines in a predictable manner (i.e., same cell count and viability profiles over time) is extremely important to ensure reproducible and optimal recombinant product yields. As cell lines grow to different maximum densities under different medium conditions, they should be subcultured at different initial cell inoculum densities. Ideally, cell lines should be subcultured by 10-fold dilution with fresh medium and allowed to grow to densities that are ≤40% of the maximum achievable cell density (for *Sf*9 in TC100/5% FCS medium, maximum density is 2×10^6 cells/ml). Above this critical density, the culture deviates from the maximum specific growth rate and may exhibit inefficient utilization of nutrients and subsequent variability in maximal production.

Viral stocks. Two major rules are associated with stock virus preparation. (1) Keep the number of times a virus is serially passaged to a minimum (<10). Otherwise, mutant virus can become the predominant species (Kool et al., 1991), leading to a subsequent decrease in recombinant product formation in infected insect cell cultures (Wickham et al., 1991). (2) Cultures serially infected at a high MOI (5 to 10) are more likely to have higher proportions of defective interfering particles than those infected at low MOI. A high cell viability (>95%) is essential for good results. A low MOI (<0.1) allows some degree of postinfection cell growth, which leads to higher numbers of infected cells and the production of high-titer viral stocks. High-titer viral stocks are necessary to prevent the need to add large quantities of viral stock inoculum to large-scale cultures employed for recombinant protein expression.

Titration of virus. The relative advantages of the plaque assay and end-point assay may be dependent on the availability of an easy marker for infection (some viruses carry β-galactosidase or luciferase as a reporter gene). Both titration methods take at least 6 days to obtain an estimate with a large error range (50% to 100%). The end-point assay, however, is technically less difficult than the plaque assay,

ECU IASTATE UNIVERSITY LIBRARY

which allows many more replicates to be made. This can reduce the error range significantly (down to 15% to 20% for 100 replicates per dilution). In this case initial dilutions can be performed in sterile 1.5-ml microcentrifuge tubes. When, in contrast to β-gal expressing viruses, the recombinant virus does not express a protein that can be quickly and easily detected in the 96-well microtiter plates, the end-point method is more difficult to interpret, and it is advisable to use the plaque assay even at the sacrifice of accuracy.

The major hurdles in virus quantification are associated with the inherent nature of the bioassay, which depends on the condition and density of the cells. Cells from poorly growing cultures with low viability cannot be used. Even for healthy cultures, however, if the cell density used is too low, underestimation of the virus titer occurs. If the cell density is too high, nutrients essential for recombinant product expression may be consumed to a large degree by cell growth, which would also lead to the underestimation of virus titers.

Expression kinetics. Evaluation of expression kinetics needs to be performed for every recombinant virus. In particular, the optimal time of harvest is a parameter that is specific to each protein. It varies largely with the virus construct (specifically, the temporal class of the viral promoter used for driving gene expression), the type of protein (i.e., cytoplasmic versus secreted), and the extent of post-translational modifications.

Initially, infection at a higher MOI (1 to 5) is desirable to establish the optimal times of infection and harvest, especially if product instability is an issue. The MOI cannot directly increase the productive capacity of individual insect cells, but a low MOI (0.01 to 0.0001) can indirectly increase the final volumetric yield due to increased postinfection cell growth. This may be useful for the large-scale expression of stable recombinant proteins and when virus stocks are dilute. A low MOI may lead to variability of product expression due to the inherent inaccuracy of the methods employed for virus stock quantification. Slight underestimation of the true low MOI leads to excessive cell growth and increases the risk of substrate limitation. Conversely, slight overestimation of the true low MOI leads to suboptimal postinfection cell growth, and therefore decreased predicted volumetric yield.

Optimal, less variable product yields can be achieved without instability concerns by optimizing the cell density at the time of infection, employing a high MOI. The cell density at the time of infection can significantly affect production yields of proteins as well as virus. For highest yields of recombinant proteins, it is necessary to infect cultures at the highest possible cell density that supports infection and maximum specific productivites. This density usually occurs immediately prior to the mid-exponential growth phase and is dependent on the medium and cell line employed.

Maintenance of separate virus and cell banks. Physical separation of all virus-associated material and equipment from cell-associated material and equipment is essential. This includes incubators, fume hoods and associated apparatus, bioreactors, probes, cell culture reagents, and media. Accidental contamination of stock cell cultures with virus is potentially disastrous and difficult to detect. Small quantities of contaminating virus may involve a latent infection that is continuously diluted during normal subculture. If a virally contaminated culture is left to overgrow, it may be difficult to detect the infection because the culture may stop growing due to exhaustion of nutrients before a full-scale viral infection can be detected.

Production in bioreactors. Expression decreases in batch cultures infected beyond the mid-exponential phase of cell growth. Dissolved oxygen (pO_2) is the major additional parameter that can be easily controlled with bioreactors compared to spinner flasks. As a general rule, a set point of 30% to 50% dissolved oxygen tension (of oxygen contained in air) should be optimal and has been shown to be fairly independent of the target protein. Because the culture is sparged either continuously or at intervals with gas, the addition of a shear protectant such as pluronic F-68 is required to avoid mechanical damage to the cells (Murhammer and Goochee, 1988).

Basic Protocol 3 describes a procedure for stirred tank reactors. Minor modifications, in particular for pO_2 control strategy, are necessary for airlift type reactors. Rice et al. (1993) compared the two reactor types and showed that they were equivalent in terms of protein expression levels. Finally, viability should be monitored closely in large-scale systems, even when the optimal time of harvest has already been established at a small scale, to avoid excessive contamination of the supernatant with cellular proteins and to facilitate subsequent downstream processing.

Media. Recombinant product expression is nutrient dependent and therefore medium de-

PSU VAN PELT LIBRARY

pendent. Serum-free medium generally supports higher expression levels due to the incorporation of greatly increased quantities of nutrients, including carbohydrates and amino acids. For instance, Sf-900 II contains five times the amount of glucose and twice the amount of glutamine as serum-containing IPL-41 medium and is able to sustain higher maximum cell densities and recombinant product yields. Absence of serum is not directly responsible for this difference, however, as serum-supplemented IPL-41 medium is more enriched and sustains higher cell growth and protein production than serum-supplemented TC100 medium. If not included in the commercial medium, the addition of pluronic F-68 (≤4 g/liter) is essential to protect the cells against the shear stress imposed by a combined sparging and mechanical agitation in bioreactors. Fetal calf serum is available from many vendors. Different lots of serum from a number of suppliers should be obtained and tested. The lot that promotes the best growth rate and cell viability should be purchased in bulk.

Antibiotics. The routine use of antibiotics to allow contaminant-free cell culture is not recommended for two reasons. Antibiotics may affect the growth and production potential of the culture. Additionally they may lead to latent bacterial infection in the stock cell cultures with possible resistance that cannot be detected until extended cell growth or during valuable production runs.

Harvesting. Establishment of the degree of sensitivity of the target protein to degradation due to cell separation and concentration protocols should be established at small-scale prior to large-scale harvest, as it is considered to be protein specific. In the case of a secreted product, concentration by ultrafiltration should directly follow cell separation. For products that are particularly sensitive to proteolysis, we find it useful to add protease inhibitors (1 mM benzamidine, 1 mM PMSF, 5 mg/liter leupeptin, 5 mg/liter SBTI, and 5 mg/liter pepstatin A) immediately after cell separation. Degradation of cytoplasmic and secreted proteins can happen very quickly at late times of infection and make the protein difficult to purify (McGlynn et al., 1992). For a secreted protein, perfusion alleviates this problem by reducing the residence time of the protein in the bioreactor (Jäger et al., 1992).

Tangential flow microfiltration can be performed by attaching the filter system directly to the reactor (see Support Protocol 3) or, alternatively, by transferring the contents of the reactor to a harvest tank and filtering the tank contents. The filter system should have a minimum of 0.04 m^2 per liter of reactor volume so as to allow complete separation in <1 hr. Microfiltration should avoid cell breakage and release of cellular proteases (see Maiorella et al., 1991). This can be difficult considering the fragility of infected cells. It should be carried out quickly (<1 hr for large volumes).

Anticipated Results

Generally, reported levels of foreign gene expression range from about 1 to 500 mg recombinant product per 2×10^9 infected cells (Luckow and Summers, 1988; Miller, 1988). Reported expression levels of 25% to 70% total cellular protein produced in infected cultures often represent viral structural proteins such as BlueTongue virus proteins (Roy, 1990) or rabies nucleoprotein (Prehaud et al., 1990). It should be emphasized that these are examples of the potential levels, and 10 to 100 mg per 10^9 infected cells is the usual expression level range for most heterologous proteins. Comparison with different eukaryotic expression systems such as those employing mammalian cell lines indicates higher production by the baculovirus expression vector system.

Time Considerations

The baculovirus life cycle dictates that 4 to 5 days after cell infection be allowed for viral reproduction. Moreover, up to 1.5 to 2 weeks may be required to achieve target cell densities of host cells before infection.

Viral stock production takes ~4 or 5 days postinfection, and, although titration experiments can be set up in 1 day, it takes at least 6 days for titers to be determined. The time required for analysis of expression in small-scale cultures, which depends on how quickly target cell densities are achieved, ranges from 7 to 10 days. Preparing samples for electrophoresis can be accomplished in ~30 min, but SDS-PAGE or other analysis procedures require 1 to 3 days. Measuring nutrient levels in culture media can range from as short as ~15 min for simple enzyme assays employing kits or electrodes to as long as 1 day if HPLC is required.

Production in bioreactors entails similar time considerations. Preparing a reactor and loading it with medium can take half a day, and it is best to observe the system for 1 or 2 days prior to inoculation to ensure sterility. Perfusion cultures can theoretically be maintained indefinitely. The time required for harvesting batch cultures depends on the volume to be

ECU IASTATE UNIVERSITY LIBRARY

processed, ranging from 30 min for batch centrifugation to 45 min for continuous feed centrifugation to 1 hr for tangential flow microfiltration. The last procedure is followed by batch centrifugation, leading to a total time of 1.5 hr.

Overview of Protein Expression in *Saccharomyces cerevisiae*

For more than a decade, the yeast *Saccharomyces cerevisiae* has been extensively utilized for the production of foreign proteins. Numerous characteristics of this system account for its popularity, among them (1) the existence of well-developed tools for manipulation of yeast DNA, including expression vectors and host strains; (2) a vast knowledge base regarding the genetics and biochemistry of the organism; (3) a eukaryotic secretory pathway; (4) eukaryotic post-translational modification pathways, such as those for N-linked and O-linked glycosylation; and (5) an extensive track record as a safe organism.

Foreign gene expression in *S. cerevisiae* has been reported for a wide variety of proteins derived from fungal and mammalian species, and many laboratories have contributed to a substantial base of vectors and host strains. Romanos et al. (1992) provide an extensive overview of strategies and progress toward the expression of foreign genes in *S. cerevisiae* as well as other yeasts. However, although *S. cerevisiae* has a well-developed eukaryotic secretory pathway, it is not the most efficient yeast for high-level export of proteins to the extracellular medium. There have been notable successes with respect to secretion of some foreign proteins in *S. cerevisiae* (Innis et al., 1985; Van Arsdell et al., 1987; Penttila et al., 1988; Hitzeman et al., 1990), but often transport to the extracellular medium is inefficient, especially for complex mammalian proteins of high molecular weight. Nevertheless, the application of advanced genetic and molecular biology tools should bring continued improvements in secretory capabilities of engineered *S. cerevisiae*.

As with all heterologous expression systems, the production of foreign proteins in *S. cerevisiae* poses various challenges, some of which have not yet been resolved. In general, the goals for expression of foreign proteins in *S. cerevisiae* are (1) attainment of desired protein yield; (2) production of protein with appropriate post-translational modifications, desired conformation, and biological function; and (3) secretion to the extracellular medium. Although these criteria do not apply to all expression projects, many proteins intended for human therapeutic use are normally secreted, and complex post-translational processing is required for biological function. It is especially for these cases that further engineering of *S. cerevisiae* vectors and host strains is required to improve both the product yield and product quality—particularly with regard to post-translational glycosylation, for which there are several important differences between *S. cerevisiae* and mammalian cells (Ballou et al., 1980; Kukuruzinska et al., 1987).

VECTORS AND HOST STRAINS

Through the efforts of a diverse and talented community, there are now many vectors and host strains available to direct gene expression in *S. cerevisiae* (Romanos et al., 1992). A variety of choices is available with respect to specific elements used to direct expression and secretion—e.g., the promoter to direct expression, the signal sequence for secretion, the expression cassette copy number and mechanism for replication, and the selectable marker to establish and/or maintain transformants. Some representative vectors that have been successfully used to direct foreign gene expression in *S. cerevisiae* are listed in Table 5.6.1. These examples illustrate the diversity of choices available to effect production of foreign proteins in this yeast.

Promoters

Many different promoters have been used to successfully direct expression of foreign genes in *S. cerevisiae*. In some cases, highly efficient promoters from the glycolytic pathway (glyceraldehyde-3-phosphate dehydrogenase, alcohol dehydrogenase, and phosphoglycerate kinase) have been used (Shuster, 1989). Because these promoters are among the strongest in *S. cerevisiae*, they are reasonable choices to effect high-level expression of foreign genes. However, these promoters should be used with care because expression is up-regulated by glucose, a common carbon source in yeast media.

Many tightly regulated, relatively strong yeast promoters are available to direct expression in *S. cerevisiae*, including those from *GAL1*, *PHO5*, and *CUP1*. In these cases, regulated expression can be achieved through simple manipulation of the growth medium by addition of metabolites or ions (Kramer et al., 1984)—galactose (*GAL1*), phosphate (*PHO5*), and copper (*CUP1*)—in a manner that will allow the transition from shaker flasks to large-scale fermentors. Through the use of these promoters, it is relatively simple to regulate the timing of expression, such as toward the end of a large-scale fermentation. In employing these and other expression systems, it is especially important to carefully consider the choice of host strain. For example, many host strains carry the *gal2* mutation, making the cells refractive to galactose import. Also, host strains vary considerably in their resistance to copper ions.

In addition to the naturally occurring regulated promoters, investigators have creatively utilized host strains carrying genetic alterations to achieve regulated expression of strong yeast promoters. For example, the *MF*-α1 (α-factor) promoter is constitutively expressed in wild-type cells of the α mating type. Brake et al. (1984) employed a *MAT*α strain carrying a mutation in the *sir3* gene (which regulates mating type–specific gene expression) to achieve temperature-regulated expression of epidermal growth factor driven by the *MF*-α1 promoter.

Vector Maintenance and Copy Number

In general, assuming the criterion of regulated expression can be achieved, high copy number of the expression cassette is considered desirable. High copy number can sometimes enhance expression levels and can result in greater stability of transformed yeast strains. To effect autonomous regulation of the expression cassette, many investigators choose the 2μm circle replication system. Copy number of vectors based on this system can vary depending on choice of selectable marker (see Selectable Markers) and range from ~10 to 200 copies per cell. An alternative approach to achieve both high copy number and stable replication is to integrate the expression cassette at repeated sites within the yeast genome. Lopes et al. (1989) developed an integrating plasmid, pMIRY2, that carries a portion of the rDNA of *S. cerevisiae* and can integrate at high copy number (greater than 100 copies) within this repetitive genomic region. Sakai et al. (1991) employed a strategy that led to integration of multiple copies of expression cassettes between δ sequences of Ty transposable elements on yeast chromosomes.

Transcription Terminators

Terminators from many yeast genes have been employed to efficiently terminate expression of heterologous mRNAs. It is difficult to discern clear differences in expression efficiencies based on the particular terminator employed, but it is important to note that inclusion of a transcription terminator in the expression cassette is desirable for assuring maximal effectiveness for the cassette.

Selectable Markers

An important consideration in developing expression vectors is the choice of selectable marker. This component can influence the ease of yeast transformation, copy number and stability of the expression cassette, and adaptability of the transformed strains for large-scale

UCLA BIOMEDICAL LIBRARY

fermentation. The most widely used selectable markers are yeast genes that complement auxotrophic mutations in host strains. These include, for example, the *LEU2* and *URA3* genes used in strains that are leu2 or ura3, respectively. Host strains have been assembled that carry very stable forms of these mutant loci, including strains that carry two lesions within the *LEU2* gene (*leu2-3* and *leu2-112*). In addition to maintenance based on auxotrophic complementation, positive selection is also available based on resistance to drugs such as G418 (Webster and Dickson, 1983) or to ions such as copper (Henderson et al. 1985). Positive selection is particularly useful for transformation of strains lacking auxotrophic mutations, especially industrial yeasts.

Selectable markers should be chosen carefully because the marker may have unexpected effects, e.g., on expression cassette copy number and ease of transformation of host strains. For example, two forms of the *LEU2* selectable marker are available, one of which (*LEU2*-d) carries only a portion of the *LEU2* promoter (Beggs, 1978; Erhart and Hollenberg, 1983). As a result, vectors carrying this marker are maintained at very high copy number, but transformation efficiencies are much reduced.

CHALLENGES TO THE EXPRESSION OF FOREIGN PROTEINS

Although the differences among expression vectors can be very subtle, effects on expression of foreign proteins can be quite profound. To illustrate this, results are presented from a series of studies on the expression of a human glycoprotein, antithrombin III (At-III; Strausberg and Strausberg, 1991). This example was chosen because it amply illustrates many of the challenges that can be encountered in attempting to attain high-level expression, post-translational modification, and secretion to the extracellular medium.

At-III is a human plasma protein with three disulfide bonds, three sites for N-linked glycosylation, and a nonglycosylated molecular weight of 43,000. A number of important goals were set for expression of this protein in *S. cerevisiae*, including (1) expression levels of at least several hundred milligrams per liter of culture; (2) proper signal processing to produce an amino acid sequence identical to that of the protein expressed in humans; (3) proper conformation, including the formation of the three disulfide bonds; (4) post-translational amino acid modification, especially N-linked glycosylation of three asparagine residues; and (5) secretion to the extracellular medium.

The potential of using *S. cerevisiae* for the production of glycosylated, biologically active At-III was initially tested using an expression vector carrying sequences known to efficiently direct secretion. A vector carrying the promoter and signal sequence from the well-characterized *MF*-α1 gene was chosen because this gene encodes an efficiently secreted yeast peptide, α-factor (see Fig. 5.6.1). In this case, secretion is directed by both pre and pro sequences; proteolytic processing of these pre and pro sequences is well understood both genetically and biochemically. Other important yeast elements included in the initial expression vectors for At-III production were a replication origin from the yeast 2μm circle (chosen because vectors with this origin replicate in a stable manner and can be maintained at medium or high copy number), a transcription terminator from the highly expressed glyceraldehyde-3-phosphate dehydrogenase (*GPD1*) gene for efficient termination, and the yeast *LEU2*-d gene as a selectable marker. (*LEU2*-d is a truncated form of the *LEU2* gene lacking a portion of the promoter region. An order-of-magnitude increase in vector copy number is associated with use of this selectable marker, compared to that of the full-length *LEU2* gene in *leu2* host strains.)

Yeast strains of *MAT***a** and *MAT*α mating types were transformed with this vector and several very striking results were obtained. First, it was clear from immunoblot analysis and biological activity assays that yeast can produce glycosylated At-III with biological activity. The At-III protein detected through the immunoblot appeared as a very heterogeneous band, indicating the addition of N-linked core glycosylation in the endoplasmic reticulum and outer chains of variable length in the Golgi complex. This pattern is very typical of yeast glycosylated proteins such as invertase (Kukuruzinska et al., 1987). Second, examination of the At-III expressed in yeast and treated with endoglycosidase H to remove carbohydrate (*UNIT 12.4*) revealed that the α-factor prepro sequence was retained in a substantial portion of the protein population. Third, overall expression was estimated at less than one percent of total cell protein. Interestingly, transformation with the high-copy-number vector (YpGX235) was only successful in cells of the *MAT*α mating type, where activity of the *MF*-α1 promoter was expected to be very low. This result suggested that high-level expression of At-III, ex-

PROTEIN SCIENCE LIBRARY

pected in *MAT*α cells, might be toxic to *S. cerevisiae*. Even at this low level of expression, most of the At-III remained cell-associated and segregated with insoluble cellular material. This result was consistent with retention of the α-factor prepro sequence.

Attainment of Desired Production Yield

To achieve regulated, high-level expression, a hybrid promoter was assembled from the yeast *GAL1* and *MF*-α1 genes. This promoter design was chosen because regulation of yeast *GAL1* is well understood and permits a variety of regulation schemes suitable for large-scale fermentation. The hybrid promoter consisted of the upstream activation site (UAS) from *GAL1* positioned upstream from the *MF*-α1 transcription initiation site. Other important elements in the vector include a combination of the 2μm origin of replication and *LEU2*-d (for high copy number) and a *GPD1* transcription terminator.

Initial expression results in yeast cells transformed with this vector were only somewhat encouraging. Although regulated expression of At-III protein was observed, the actual production levels were still quite low, possibly due to the limited availability of regulatory proteins associated with expression from the *GAL1* promoter. In this system, inducible expression is dependent upon a *trans*-acting regulatory protein, GAL4, that interacts with the UAS (Johnston, 1987). In the absence of galactose, GAL4 complexes with another protein, GAL80, and is unavailable for interaction with the UAS. Upon induction with galactose, GAL4 protein dissociates from GAL80 and binds to the UAS, thereby stimulating protein induction. It was known that the GAL4 protein is available in very limited quantities in wild-type yeast cells, so it seemed reasonable that most of the copies of the hybrid *GAL1/MF*-α1 promoter might remain dormant. Therefore, an additional modification was made so that the *GAL4* gene was positioned within the high-copy-number expression vector. The results were again only moderately encouraging because, although expression was increased several fold, the overall expression levels were no more than a few percent of total soluble protein. Immunoblot analysis revealed that ~90% of the At-III remained associated within the insoluble cell fraction.

A very striking impact on expression of At-III resulted from the use of different signal peptide coding sequences upstream from the start of mature At-III. The main goal in assessing the use of different sequences was to assess the impact on secretion, but the most noteworthy result was observed with respect to effect on expression level. Vectors were assembled

[b]Determined by radioimmunoassay.

with signal sequences derived from various secreted proteins including invertase (SUC2), α-factor (MF-α1), and acid phosphatase (PHO5; see Fig. 5.6.1). For extensive discussions of signal sequences used to direct secretion in yeast see Kingsman et al. (1985) and Romanos et al. (1992). Each of the signal peptide coding sequences was assembled through insertional directed mutagenesis so that no extraneous codons were present between the signal peptide and mature protein coding sequences. For this experiment, the PHO5 signal peptide was designed predominantly from preferred yeast codons, the codons most often utilized in highly expressed yeast genes. Expression levels were monitored by radioimmunoassay and immunoblotting.

These studies were very enlightening with regard to parameters that can influence expression levels for foreign proteins in *S. cerevisiae*. First, upon induction, expression levels of soluble At-III (most of the At-III is insoluble) differed by more than an order of magnitude among the different vectors (Table 5.6.2). This result was most striking in the case of YpGX262GAL4, in which secretion is directed by the PHO5 signal. In this case, At-III protein accumulated to ~20 percent of total cell protein and microscopic examination of the yeast cells revealed particulate bodies reminiscent of the inclusion bodies associated with high-level protein expression in *Escherichia coli*. Although the mechanism for the very high level of At-III expression associated with this vector was not determined, a reasonable interpretation is that the use of preferred codons in the PHO5 signal peptide coding sequence enhanced translation initiation.

Production of Protein with Appropriate Post-translational Modifications, Conformation, and Function

One of the most difficult issues concerning production in yeast of glycoproteins intended for human therapy is the difference in glycosylation patterns for both N- and O-linked glycosylations. Although N-linked glycosylation in the endoplasmic reticulum in yeast is quite similar to that in mammals, substantial differences are associated with processing in the Golgi complex. In the endoplasmic reticulum, both systems add core units composed of mannose, *N*-acetylglucosamine, and glucose residues, and processing of certain glucose and mannose residues follows. However, in the Golgi complex, mammalian cells continue to process mannose residues and additional residues such as galactose and sialic acid. In contrast, *S. cerevisiae* performs neither of these functions, but instead adds extensive outer chains with many branches that can be heterogeneous in size.

Genetic approaches have been employed to facilitate the production in yeast of glycoproteins more similar to their human counterparts. Ballou and colleagues (Ballou et al., 1980) provided a basis for this approach based on careful genetic dissection of the glycosylation pathway. For example, yeast strains with the *mnn9* mutation do not add further mannose units in the Golgi complex. In the case of At-III, use of strains carrying this mutation resulted in production of a homogeneous protein with only core glycosylation. Further utilization of the *mnn* family of mutations may permit engineering of yeast-produced glycoproteins with improved properties.

Expression levels can markedly affect post-translational modification of foreign proteins. Thus, in the At-III example, expression at relatively low levels resulted in protein that carried full glycosylation, including inner and outer chains. However, as expression was enhanced, glycosylation was reduced, and at high-level expression directed by YpGX262, most of the At-III was unglycosylated. This results, of course, from the important interplay that occurs between the expression level and

BRUNEL UNIVERSITY LIBRARY

the ability of yeast cells to process the molecules during their transport through the secretory pathway.

Secretion to the Extracellular Medium

Although some success has been obtained in secreting complex mammalian proteins extracellularly from *S. cerevisiae*, the greatest success has only been achieved with smaller peptides or proteins normally secreted by fungal sources. Indeed, in the At-III example, no extracellular protein was detected. Other yeasts appear to secrete mammalian proteins more effectively, posing a major challenge to the future of *S. cerevisiae* as the system of choice for secreted proteins. However, increased understanding of yeast genetics and biochemistry may be used to substantially improve secretion of foreign proteins in *S. cerevisiae*.

Transport of proteins through a eukaryotic secretory pathway is a complex process involving the participation of many cofactors. For instance, signal peptidase activity is required for removal of signal sequences from mature proteins. In the case of α-factor, additional proteases encoded by the *KEX2* and *STE13* genes are required for cleavage of the pro sequence from the mature peptide. Thus, it is possible that with overexpression of secreted proteins, these cofactors become limiting. This is supported by the observation of Haguenauer-Tsapis and Hinnen (1984) that upon overexpression of yeast acid phosphatase, precursor protein accumulates. In some cases, overexpression of limited processing enzymes has a beneficial effect. Barr et al. (1987) noted that multiple copies of *KEX2* enhanced the ability of *S. cerevisiae* to process and secrete a foreign protein, transforming growth factor, linked to the α-factor prepro sequence. Therefore, careful examination of processing defects can identify limited processing enzymes within the cell and their increased expression can, at least in some cases, improve processing and secretion.

In addition to protease activities, many other protein functions are required for efficient secretion. The activity of several accessory proteins is required for proper conformational folding within the endoplasmic reticulum—e.g., molecular chaperones as well as proteins specifically associated with disulfide bond formation. Robinson et al. (1994) reported that overexpression of protein disulfide isomerase, an enzyme that catalyzes disulfide exchange within the endoplasmic reticulum, resulted in improved secretion of both human platelet-derived growth factor B homodimer and *Schizosaccharomyces pombe* acid phosphatase from *S. cerevisiae*.

Furthermore, the ease of *S. cerevisiae* genetic manipulation offers the potential for improved secretion even in cases where specific defects have not been identified. Toward that end, several groups have applied mutagenesis strategies in conjunction with rapid screening methods to identify yeast strains with enhanced secretion capability. Smith et al. (1985) applied this approach to identify yeast strains that carried mutations leading to enhanced secretion of chymosin. Importantly, improved secretion of additional, but not all, foreign proteins was associated with one of these mutations.

TIME FRAME AND FUTURE PROSPECTS

As summarized in this commentary, tools for the expression of foreign genes in *S. cerevisiae* are very well developed, and allow the individual researcher to establish within a few months the relative capabilities of *S. cerevisiae* as a host for expression of new target proteins. However, in many cases the challenges are substantial and long-term dedicated efforts are required for ultimate success. Prospects for further engineering of *S. cerevisiae* cells for the expression of foreign proteins seem quite bright, in part because a cooperative international effort is likely to soon complete the entire sequence of the *S. cerevisiae* genome. The availability of a complete repertoire of genetic information will provide a very firm basis for better understanding of complex eukaryotic pathways, and will likely suggest new avenues for engineering this organism for enhanced expression of complex mammalian proteins.

Overview of Protein Expression in *Pichia pastoris*

During the early 1970s, the methylotrophic yeast *Pichia pastoris* was developed as a biological tool to convert methanol—a cheap and readily available carbon source that was being discarded by the oil industry as a waste product—into high-quality protein that could be used in the livestock industry. A combination of the oil crisis that began in the mid-1970s, the fact that *Pichia* as a component of livestock feed was never able to compete in cost with soybeans, and the emergence of the biotechnology industry led to new attempts to find potential uses for the high protein-production capacity of *Pichia*. By the early 1980s the focus had shifted to the use of *Pichia* as a eukaryotic microbial system to produce large quantities of heterologous proteins of interest to biotechnologists, including those in the pharmaceutical industry (Ratner, 1989; Wegner, 1990; Buckholz et al., 1991; Cregg et al., 1993). The successful and rapid introduction of *P. pastoris* into the general scientific community as a heterologous expression system is a result of several important factors, including the goal of developing *P. pastoris* into a single-cell protein (SCP) production system, its utility as a model eukaryotic organism for basic molecular and cellular biology studies (Gould et al., 1992), and its similarity—both biologically and technically—to one of the most well-characterized systems in modern biology, the baker's yeast *Saccharomyces cerevisiae* (UNIT 5.6).

The exploitation of *Pichia* as a tool to produce useful quantities of biologically relevant proteins has moved into high gear (see Table 5.7.1). *Pichia* as an expression system is now readily available to the research community and can be used to generate proteins destined for academic scrutiny in addition to proteins produced in *Pichia* for commercialization. The number of heterologous proteins successfully being expressed in *Pichia* is doubling almost monthly.

GENERAL CHARACTERISTICS OF *PICHIA PASTORIS*

As a yeast, *Pichia pastoris* is a microbial eukaryote and is as easy to manipulate as *Escherichia coli*. It has many of the advantages of eukaryotic expression (e.g., protein processing, folding, and post-translational modifications), and it is faster, easier, and cheaper to use than other eukaryotic expression systems, such as baculovirus (UNITS 5.4 & 5.4) or mammalian tissue culture. It also generally gives higher expression levels.

P. pastoris is completely amenable to the genetic, biochemical, and molecular biological techniques that have been developed over the past several decades for *S. cerevisiae* with little or no modification. In particular, methods for transformation by complementation, gene disruption, and gene replacement developed for *S. cerevisiae* work equally well for *P. pastoris* (Cregg et al., 1987, 1989; Guthrie and Fink, 1991). In addition, heterologous protein expression levels are often 10- to 100-fold higher in *Pichia*.

The genetic nomenclature adopted for *P. pastoris* mirrors that used for *S. cerevisiae*. For example, the gene from *S. cerevisiae* that encodes the enzyme histidinol dehydrogenase is called the *HIS4* gene; the homologous gene from *P. pastoris* is called the *P. pastoris HIS4* gene, and so on. There is also a very high degree of cross-functionality between *P. pastoris* and *S. cerevisiae*. For instance, many *S. cerevisiae* genes have been shown to genetically complement the comparable mutants in *P. pastoris*, and vice versa—e.g., the *P. pastoris HIS4* gene functionally complements *S. cerevisiae his4* mutants, and the *S. cerevisiae HIS4* gene functionally complements *P. pastoris his4* mutants. Other cross-complementing genes that have been identified include *LEU2*, *ARG4*, *TRP1*, and *URA3*.

P. pastoris as a Methylotrophic Yeast

P. pastoris, one of four different genera of methylotrophic yeasts (the others being *Candida*, *Hansenula*, and *Torulopsis*), is capable of metabolizing methanol as its sole carbon source. The first step in this process is the oxidation of methanol to formaldehyde by the enzyme alcohol oxidase, generating hydrogen peroxide in the process. To avoid hydrogen peroxide toxicity, methanol metabolism takes place within a specialized cell organelle, the peroxisome, which sequesters toxic intermediates from the rest of the cell. Alcohol oxidase is sequestered in the peroxisomes and functions as a homo-octomer, with each subunit containing one noncovalently bound flavin adenine dinucleotide (FAD) cofactor. Alcohol oxidase

PCU IAS / CENTRAL UNIVERSITY LIBRARY

has a poor affinity for O_2 and *P. pastoris* compensates for this by generating large amounts of the enzyme.

There are two genes in *P. pastoris* that code for alcohol oxidase—*AOX1* and *AOX2*—but the *AOX1* gene is responsible for the vast majority of alcohol oxidase activity in the cell. Expression of the *AOX1* gene is tightly regulated and is induced by methanol to very high levels, typically ≥30% of the total soluble protein in cells grown with methanol as the carbon source. The *AOX1* gene has been isolated and a plasmid-borne version of its promoter is used to drive expression of the gene of interest encoding a desired heterologous protein (Ellis et al., 1985; Tschopp et al., 1987a; Koutz et al., 1989). Expression of the *AOX1* gene is controlled at the level of transcription. In methanol-grown cells ~5% of the polyA$^+$ RNA is from the *AOX1* gene. Regulation of the *AOX1* gene is similar to regulation of the *GAL1* gene (and others) of *S. cerevisiae* in that control involves a two-step process: a repression/derepression mechanism plus an induction mechanism. However, unlike the situation in *S. cerevisiae*, derepression alone of the *AOX1* gene (i.e., absence of a repressing carbon source such as glucose) is not sufficient to generate even minute levels of expression from the *AOX1* gene. The inducer, methanol, is also necessary to obtain even minimally detectable levels of *AOX1* expression (Ellis et al., 1985; Tschopp et al., 1987a; Koutz et al., 1989).

Loss of the *AOX1* gene (see Transformation by Integration), and thus a loss in most of the cell's alcohol oxidase activity, results in a strain that is phenotypically Mut^S (methanol utilization slow). This phenotype is caused by the loss of the alcohol oxidase activity encoded by the *AOX1* gene, which results in the cell's inability to metabolize methanol. Thus, a poor growth phenotype on methanol media is observed. (Mut$^+$ strains are wild type and capable of metabolizing methanol as their sole carbon source.)

HETEROLOGOUS PROTEIN EXPRESSION

P. pastoris has been used successfully to express a wide range of heterologous proteins as either intracellular or secreted proteins (see Table 5.7.1). Secretion requires the presence of a signal sequence on the expressed protein to target it to the secretory pathway. Although several different secretion signal sequences have been used successfully, including the native secretion signal present on some heterologous proteins, success has been variable. The secretion signal sequence from the *S. cerevisiae MATα* factor prepro peptide (*MF*-α1) has been used with the most success (Cregg et al., 1993; Scorer et al., 1993).

The major advantage of expressing heterologous proteins as secreted proteins is that *P. pastoris* secretes very low levels of native proteins. That, combined with the very low amount of protein in the minimal *Pichia* growth medium, means that the secreted heterologous protein comprises the vast majority of the total protein in the medium, and this serves as a first step in purification of the expressed protein (Barr et al., 1992).

Strains for Expression

The *P. pastoris* host strains have defects in either the histidinol dehydrogenase activity encoded by the *HIS4* gene (strains GS115, KM71, SMD1163, SMD1165, and SMD1168), or the arginosuccinate lyase activity encoded by the *ARG4* gene (strain GS190), or both (strain PPF1; see Table 5.7.2). All of these strains will grow on complex media such as YPD (yeast

Table 5.7.2 Some Strains of *Pichia pastoris* Used for Heterologous Protein Expression

Strain	Genotype	Feature	Vector selectable marker required
GS115	*his4*	Wild-type strain	*HIS4*
GS190	*arg4*	Wild-type strain	*ARG4*
KM71	*his4 arg4 aox1::ARG4*	Mut^S	*HIS4*

Table 5.7.3 Media for *Pichia pastoris*

Media[a]	YNB[b]	$(NH_4)_2SO_4$	Peptone	Yeast extract	Carbon source[c]	Phosphate buffer[d]	Other	Use
YPD	—	—	2%	1%	2% glu	—	—	Rich medium
RDB[e]	0.34%	1%	—	—	2% glu	—	1 M sorbitol	Transformation
MD[f]	0.34%	1%	—	—	2% glu	—	—	Mut^+/Mut^S
MM[f]	0.34%	1%	—	—	0.5% meth	—	—	Mut^+/Mut^S
MGY	0.34%	1%	—	—	1% gly	—	—	Expression
MM	0.34%	1%	—	—	0.5% meth	—	—	Expression
BMGY[g]	0.34%	1%	2%	1%	1% gly	100 mM	—	Alternate expression
BMMY	0.34%	1%	2%	1%	0.5% meth	100 mM	—	Alternate expression

[a]All of these media can be made either as liquid or, by adding agarose to 2% (w/v), as plates.

[b]Yeast nitrogen base without amino acids and without $(NH_4)_2SO_4$.

[c]Abbreviations: glu, glucose (same as dextrose); gly, glycerol; meth, methanol.

[d]Stock: 1 M potassium phosphate buffer, adjusted to desired pH between 5 and 8.

[e]No amino acid supplements; these media are normally used with transformed strains that are His^+ (or Arg^+) prototrophs.

[f]MD and MM media can be used to identify Mut^S clones. Growth of both Mut^+ and Mut^S clones will be wild type on MD medium. Growth of Mut^+ will be wild type on MM medium, but growth of Mut^S on MM will be severely retarded to completely absent after 2 days because of the inability of Mut^S clones to efficiently metabolize methanol as a carbon source.

[g]The addition of yeast extract and peptone to expression media may improve the results of heterologous protein expression in some cases. The mode of action of this improvement is not known, but it may be that yeast extract and peptone serve as competitive inhibitors of proteases and/or act as weak medium buffering agents.

extract, peptone, dextrose) and on minimal media, such as MD (minimal dextrose), MM (minimal methanol), and MGY (minimal glycerol), that have been supplemented with histidine and/or arginine (Table 5.7.3). Until transformed with the appropriate vectors, these strains will not grow on minimal medium lacking histidine (those strains with genotype including *his4*) or arginine (those strains with genotype including *arg4*). Selection of His^+ or Arg^+ prototrophs among *his4/arg4* mutant strains transformed with a plasmid carrying the wild-type gene is used as the basis for selecting recombinant strains containing the expression plasmid.

Most expression experiments begin with wild-type strain GS115 (*his4*) in which vectors carrying the *HIS4* gene can be selected, but there are several alternative strains, mostly derivatives of GS115, that can be employed to achieve success empirically or when a specific need can be predicted. Both Mut^+ and Mut^S as well as single- and multicopy vector recombinant versions of GS115 can be generated.

KM71 (*his4 arg4 aox1::ARG4*) is a Mut^S strain because the chromosomal *AOX1* gene has been replaced with the *ARG4* gene. It can be used when only Mut^S recombinant strains are desired (see Table 5.7.2).

SMD1163 (*his4 pep4 prB1*), SMD1165 (*his4 prB1*), and SMD1168 (*his4 pep4*) are a series of protease-deficient strains that may provide a more suitable environment for certain proteins that are being expressed as heterologous proteins. The *PEP4* gene codes for proteinase A, a vacuolar aspartyl protease required for activation of other vacuolar proteases such as carboxypeptidase Y and proteinase B. Prior to processing and activation by proteinase A, proteinase B has about half of its protease activity. The *PRB1* gene codes for proteinase B itself. Therefore, *pep4* mutants display a substantial decrease in or elimination of proteinase A and carboxypeptidase Y activity, and partial reduction in proteinase B activity. *prB1* mutants show a substantial decrease in or elimination of proteinase B activity only, and *pep4 prB1* double mutants show a substantial reduction in or elimination of all three of these protease activities (see Table 5.7.4).

Expression Plasmids

Plasmid vectors designed for heterologous protein expression in *P. pastoris* all have general features in common. These are illustrated in the generic plasmid depicted in Figure 5.7.1. (1) The $5'P_{AOX1}$ is the promoter from the *Pichia* alcohol oxidase (*AOX1*) gene; it is used to drive

CSU MORGAN LIBRARY

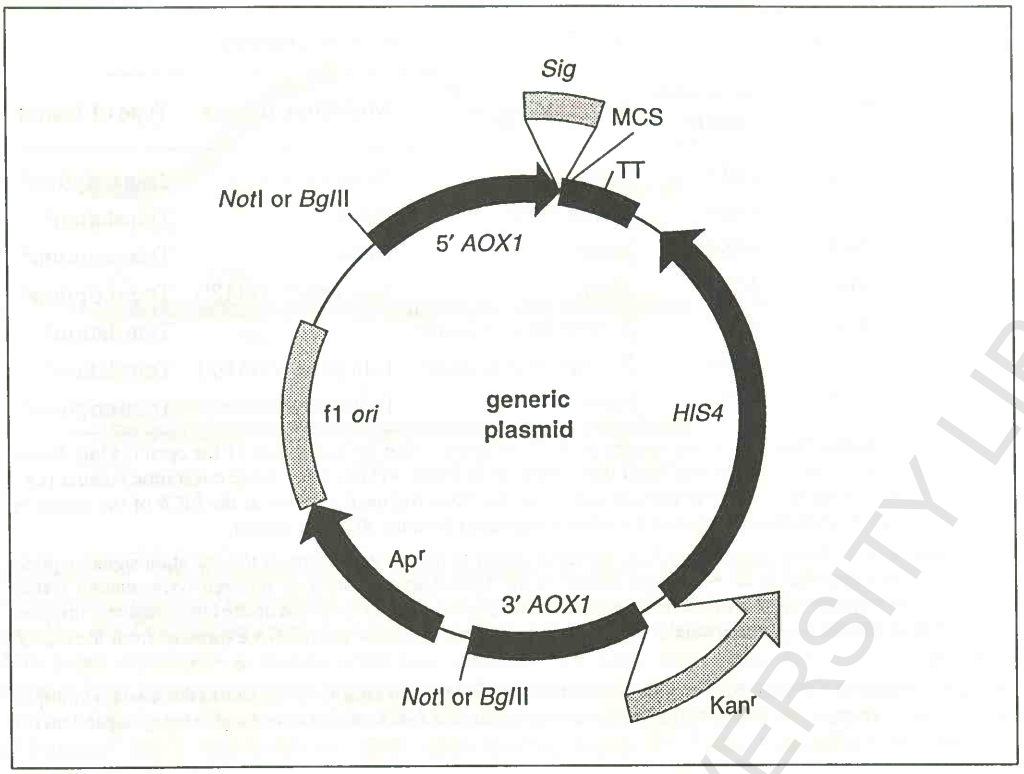

Figure 5.7.1 Generic plasmid for heterologous protein expression in *Pichia pastoris*. Elements present in all expression plasmids are shown in dark boxes, optional elements present in some plasmids are shown in gray boxes. Abbreviation: TT, transcriptional termination sequence.

methanol-inducible expression of the gene of interest. (2) The MCS is a multiple cloning site with unique restriction endonuclease sites; it is used to insert the gene of interest into the plasmid. (3) Transcription termination sequences (TT) are derived from the native *Pichia AOX1* gene; they are used to promote efficient mRNA processing and polyadenylation. (4) *HIS4*, the wild-type gene for histidinol dehydrogenase, is a selectable marker; it is used to positively select for recombinant *Pichia* strains that have acquired the vector, which complements the auxotrophic *his4* mutation. (5) The 3′*AOX1* sequence is derived from a region of the native gene that lies 3′ to the transcription termination sequences; it is required for integration of vector sequence by gene replacement or gene insertion 3′ to the chromosomal *AOX1* gene. (6) The ColE1 origin of replication and ampicillin resistance gene (Ap^r) are required for replication and maintenance in bacteria. (7) Unique restriction endonuclease sites are included that allow for the generation of linear plasmids that can integrate at the *AOX1* locus by gene replacement (*Not*I and *Bgl*II). Other unique sites at 5′P_{AOX1} (*Sac*I and *Bst*XI) and *HIS4* (*Sal*I and *Stu*I) are included to allow generation of a linear plasmid that can integrate into the genome at these loci by gene insertion.

There are several additional features that are included in some expression vectors; these serve as tools for specialized functions (see Fig. 5.7.1 and Table 5.7.4). Sig is a DNA sequence juxtaposed between 5′P_{AOX1} and the MCS region; it encodes a protein secretion signal that is expressed as an N-terminal fusion to the protein of interest. This sequence directs the passage of the protein through the secretory pathway and targets proteins that carry it out of the cell. Sig sequences that have been used for expression in *Pichia* include the *S. cerevisiae* mating type α prepro sequence (MF-1α prepro; Scorer et al., 1993, 1994), the *Pichia* acid phosphatase signal sequence (*PHO*), the *S. cerevisiae* invertase signal sequence (Tschopp et al., 1987b), and several hybrid sequences (Larouche et al., 1994). Alternatively, the gene of interest may contain a sequence that encodes its own native secretion signal; that signal sequence may be functional in *Pichia* (Digan et al., 1989; Barr et al., 1992; Despreaux et al., 1993). Kan^r is a bacterial kanamycin resistance gene; it may be included to confer resistance to the drug G418. Recombinant *Pichia* strains that contain multiple copies of Kan^r are resistant to

[a]*Transcription fusion:* Vector does not supply an ATG initiation codon for translation of the open reading frame contained within the expressed insert; insert must bring an in-frame ATG in a favorable eukaryotic context (i.e., Kozak consensus sequence); gene of interest carried on the DNA fragment inserted at the MCS of the vector is fused within the 5′ untranslated region of the mRNA expressed from the *AOX1* promoter.

[b]*Translation fusion:* Vector supplies an ATG initiation codon to initiate translation of the secretion signal peptide destined to be expressed as an N-terminal fusion to the heterologous protein of interest; open reading frame contained within insert may or may not have an in-frame ATG; gene of interest carried on the DNA fragment inserted at the MCS of the vector is fused within the open reading frame region of the mRNA expressed from the *AOX1* promoter.

[c]*Kan gene:* Bacterial Kan gene confers resistance to the drug G418; recombinant *Pichia* strains that contain multiple copies of the Kan gene can be resistant to higher concentrations of G418, with this resistance being dependent on Kan gene copy number.

higher concentrations of G418 in a manner that correlates with the Kan^r copy number. The f1 ori sequence is a bacterial single-strand origin of replication; this sequence can be included to generate single-stranded DNA in *Escherichia coli* to facilitate plasmid mutagenesis.

Transformation by Integration

As in *S. cerevisiae*, linear DNA can generate stable transformants of *P. pastoris* via homologous recombination between the transforming DNA and regions of homology within the genome (Cregg et al., 1985, 1989). Such integrants show extreme stability in the absence of selective pressure, even when present in multiple copies.

The most commonly used expression vectors carry the *HIS4* gene for selection and are designed to be linearized with a restriction enzyme such that His^+ recombinants can be generated by vector integration at the *his4* or *AOX1* locus (see Fig. 5.7.2). Integration events at the *AOX1* locus can occur as either gene insertions or gene replacements.

A gene replacement (omega insertion) event arises from a double cross-over between the *AOX1* promoter and 3′*AOX1* regions of the vector and genome; this results in the complete removal of the *AOX1* coding region (i.e., gene replacement; Fig. 5.7.2). The resulting phenotype is His^+ Mut^S. His^+ transformants can be readily and easily screened for their Mut phenotype, with Mut^S serving as a phenotypic indicator of integration via gene replacement at the *AOX1* locus.

Gene insertion events at the *AOX1* locus arise from a single cross-over event between the *AOX1* locus in the chromosome and any of the three *AOX1* regions on the vector (*AOX1* promoter, *AOX1* TT, or 3′ *AOX1*); these events result in the insertion of one or more copies of the vector upstream or downstream of an otherwise intact and functional native *AOX1* gene (see Fig. 5.7.3). The phenotype of such a transformant is His^+ Mut^+ (Mut^+ is wild-type for methanol utilization); the His^+ transformant is still able to utilize methanol because the *AOX1* gene remains intact and functional (see Fig. 5.7.3). Gene insertion events at the *his4* locus arise from a single cross-over event between the *his4* locus in the chromosome and the *HIS4* gene on the vector, and result in the insertion of one or more copies of the vector at the *his4* locus (see Fig. 5.7.4). Because the genomic *AOX1* locus is not involved in this recombination event, the phenotype of such a His^+ transformant remains Mut^+.

Multiple gene insertion events at a single locus in a cell do occur spontaneously, with a low but detectable frequency—between 1% and 10% of all selected His^+ transformants (see Fig. 5.7.5). Multicopy events can occur as gene

SCUI IAST CENTRAL UNIVERSITY LIBRARY

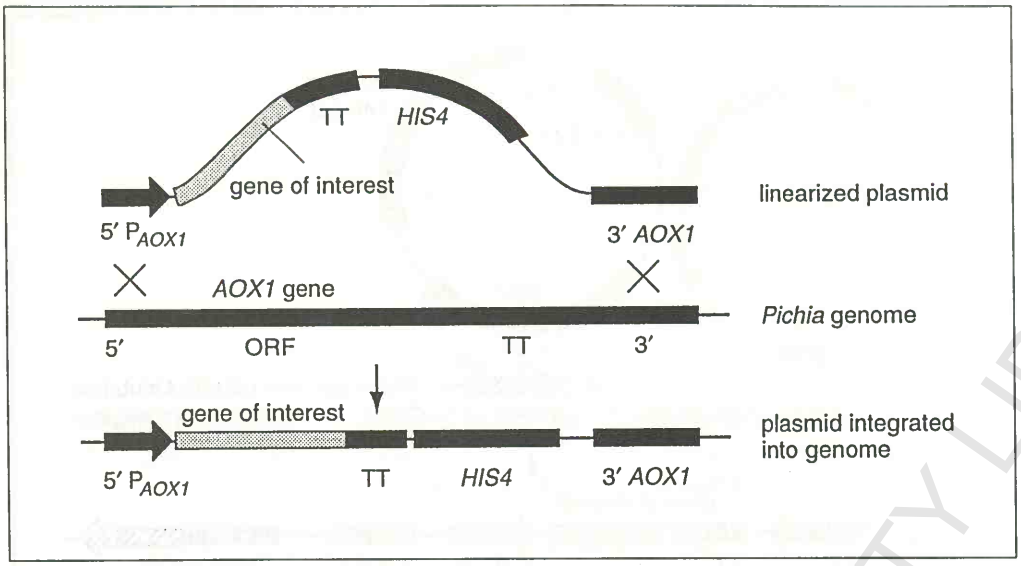

Figure 5.7.2 Gene replacement. A gene replacement event at the *AOX1* locus by a plasmid fragment carrying an "expression cassette" consisting of an *AOX1* promoter–driven gene of interest and the *HIS4* selectable marker allows for selection of His^+ prototrophs using a *his4 Pichia* strain. The event represents a double cross-over between two linear DNA molecules. Double-stranded ends of DNA molecules act to target and stimulate homologous recombination. The result is a loss of the *AOX1* locus (the strain becomes Mut^S) and the gain of P_{AOX1}-gene of interest-*HIS4* (gene of interest$^+$ His^+). Abbreviations: ORF, open reading frame; TT, transcriptional termination sequence.

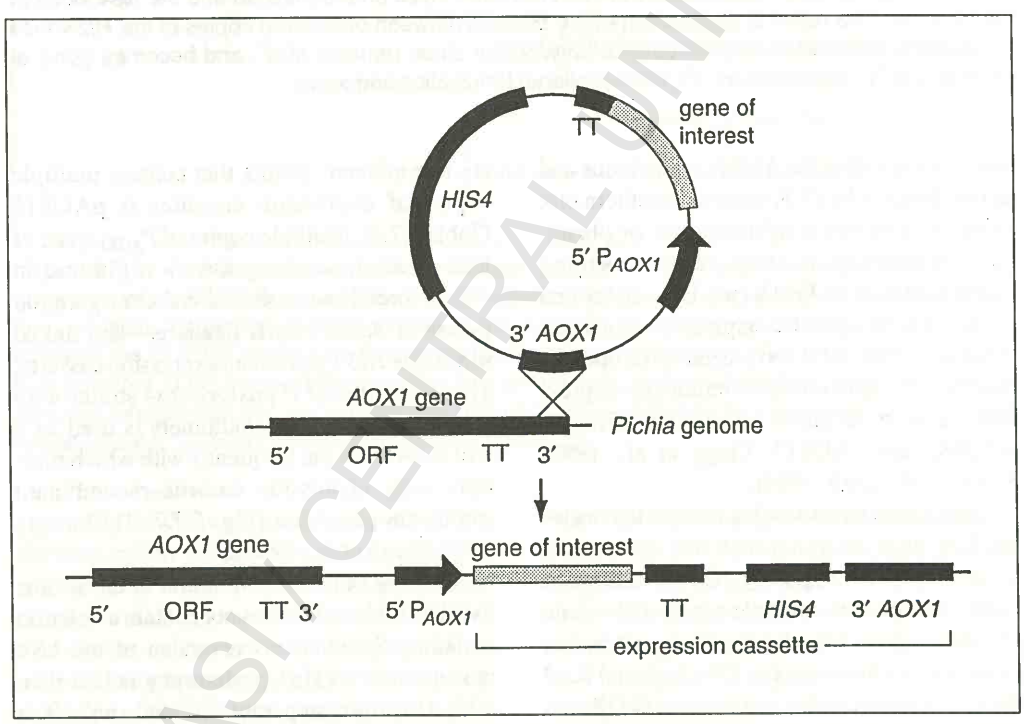

Figure 5.7.3 Gene insertion. A gene insertion event 3′ of *AOX1* in the genome by the plasmid carrying an expression cassette allows for selection of His^+ prototrophs using a *his4 Pichia* strain. The event represents a single cross-over event between circular and linear DNA molecules. Recombination takes place within regions of homology between the plasmid and the genome. The result is an insertion of the plasmid 3′ to the intact *AOX1* locus (the strain remains Mut^+) and the gain of P_{AOX1}-gene of interest-*HIS4* (gene of interest$^+$ His^+). This event also could have taken place between the 5′ *AOX1* regions on the plasmid and genome with the resulting insertion positioned 5′ to an intact *AOX1* locus. Abbreviations: ORF, open reading frame; TT, transcriptional termination sequence.

UNSW CENTRAL UNIVERSITY LIBRARY

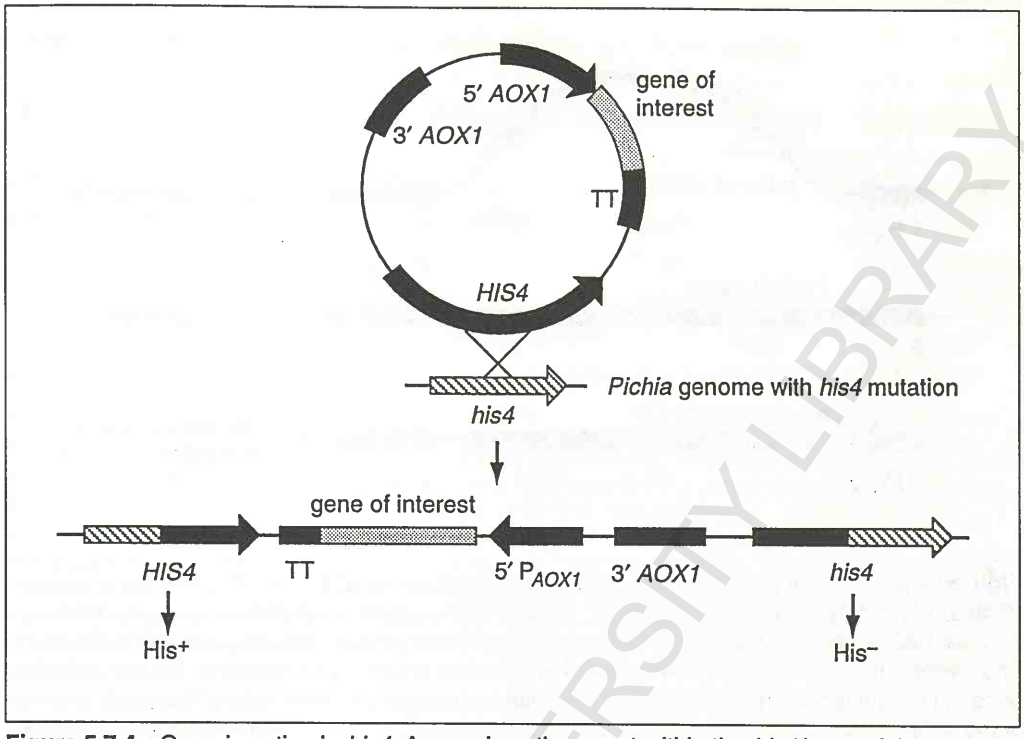

Figure 5.7.4 Gene insertion in *his4*. A gene insertion event within the *his4* locus of the genome by the plasmid carrying an expression cassette allows for selection of His$^+$ prototrophs using a *his4 Pichia* strain. The event consists of a single cross-over between circular and linear DNA molecules, in which recombination takes place between the *HIS4* locus on the plasmid and the *his4* locus in the genome. The result is an insertion of the plasmid between duplicated copies of the *HIS4/his4* genes, one still mutant and the other wild-type (the strain remains Mut$^+$, and becomes gene of interest$^+$ His$^+$). Abbreviations: TT, transcriptional termination sequence.

insertions at either the *AOX1* or *his4* locus and can be detected by PCR analysis, Southern blot analysis, differential hybridization, or phenotypic identification based on the resulting hyperresistance to G418 (see Figs. 5.7.5 and 5.7.6). Three specific expression plasmids listed in Table 5.7.4 have been developed to facilitate the generation of multicopy expression cassette recombinant strains, pPIC3K, pPIC9K, and pAO815 (Cregg et al., 1993; Scorer et al., 1993, 1994).

Expression plasmids that contain the bacterial Kan^r gene act as a marker that can be used to identify phenotypically His$^+$ recombinant strains which carry multiple copies of the gene of interest (see Fig. 5.7.6). Each expression cassette introduces a copy of the bacterial Kan^r gene. This gene confers resistance to G418, and multiple copies of the gene make recombinant strains hyperresistant to the drug G418. Hyperresistance to G418 allows for phenotypic identification of strains carrying multiple copies of the Kan^r gene and, by linkage, multiple copies of the expression cassette (P_{AOX1}-gene of interest and *HIS4*; Scorer et al., 1993, 1994).

Another plasmid system designed to generate recombinant strains that contain multiple copies of expression cassettes is pAO815 (Table 5.7.4). Multiple copies of P_{AOX1}-gene of interest are ligated together in a plasmid in vitro—forced into a directional configuration by use of *Bam*HI-*Bgl*II ligations—and linked to a single *HIS4* gene in an expression cassette. Transformation of *P. pastoris his4* strains with these in vitro–formed multimers is used as a tool to increase the frequency with which multiple copy expression cassette–recombinant strains are generated (Fig. 5.7.7; Thill et al., 1990; Cregg et al., 1993).

The *his4* mutant allele found in the strains listed in Table 5.7.2 does not contain a deletion mutation. Spontaneous reversion of the *his4* mutant allele to His$^+$ prototrophy is less than 10^{-8}. However, apparent "hit-and-run" gene conversion events of *his4* strains transformed with a *HIS4* plasmid—that is, nonintegrative recombination between the *his4* gene on the chromosome and the *HIS4* gene on the plasmid that results in conversion of the chromosomal *his4* gene to His$^+$—occurs with a frequency of 10% to 50% of all His$^+$ transformants. The His$^+$ gene conversion frequency apparently can vary

BCU IAS CENTRAL UNIVERSITY LIBRARY

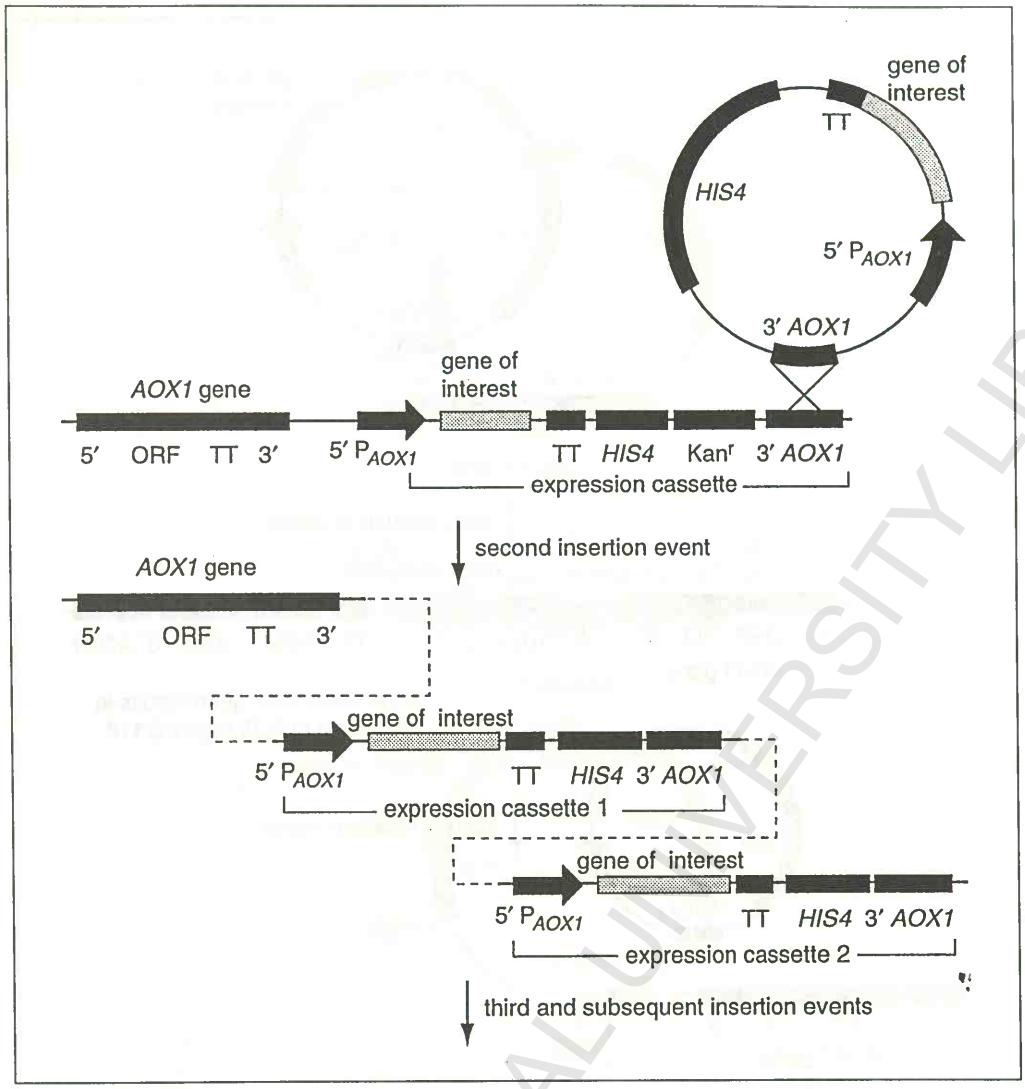

Figure 5.7.5 Multiple insertion events. Multiple insertions of an expression plasmid 3′ to an otherwise intact *AOX1* locus can result from multimer formation prior to a single insertion event or from multiple sequential insertion events at the same locus. These events can also take place between the 5′ *AOX1* regions on the plasmid and genome, with the resulting insertions positioned 5′ to an intact *AOX1* locus. Multiple events (two or more plasmids integrated) occur spontaneously, although infrequently, accounting for 1% to 10% of all His^+ transformants. Abbreviations: ORF, open reading frame; TT, transcriptional termination sequence.

depending on the transformation method, with electroporation yielding a higher frequency of His^+ gene conversion than spheroplast transformation (D.R.H., unpub. observ.). These His^+ convertants that do not contain a copy of the gene to be expressed can be identified by PCR or Southern blot analysis and eliminated from subsequent protein-expression testing.

Figure 5.7.8 outlines the steps required to generate and analyze recombinant strains of *P. pastoris*.

Post-Translational Modifications

P. pastoris utilizes most of the post-translational modification pathways typically associated with higher eukaryotes. In comparison to *S. cerevisiae*, *Pichia* may have an advantage in the glycosylation of secreted proteins because it may have less of a tendency to hyperglycosylate. Although both *S. cerevisiae* and *P. pastoris* have a majority of N-linked glycosylation of the high-mannose type, the length of the oligosaccharide chains added post-translationally to proteins is much shorter in *Pichia* than in *S. cerevisiae* (an average 8 to 14 mannose residues per side chain in *P. pastoris* compared to 50 to 150 in *S. cerevisiae*; Tschopp et al., 1987b; Grinna and Tschopp, 1989). There is also a difference between *S. cerevisiae* and *P. pastoris* in the structure of the oligosaccharides added.

CHITIT

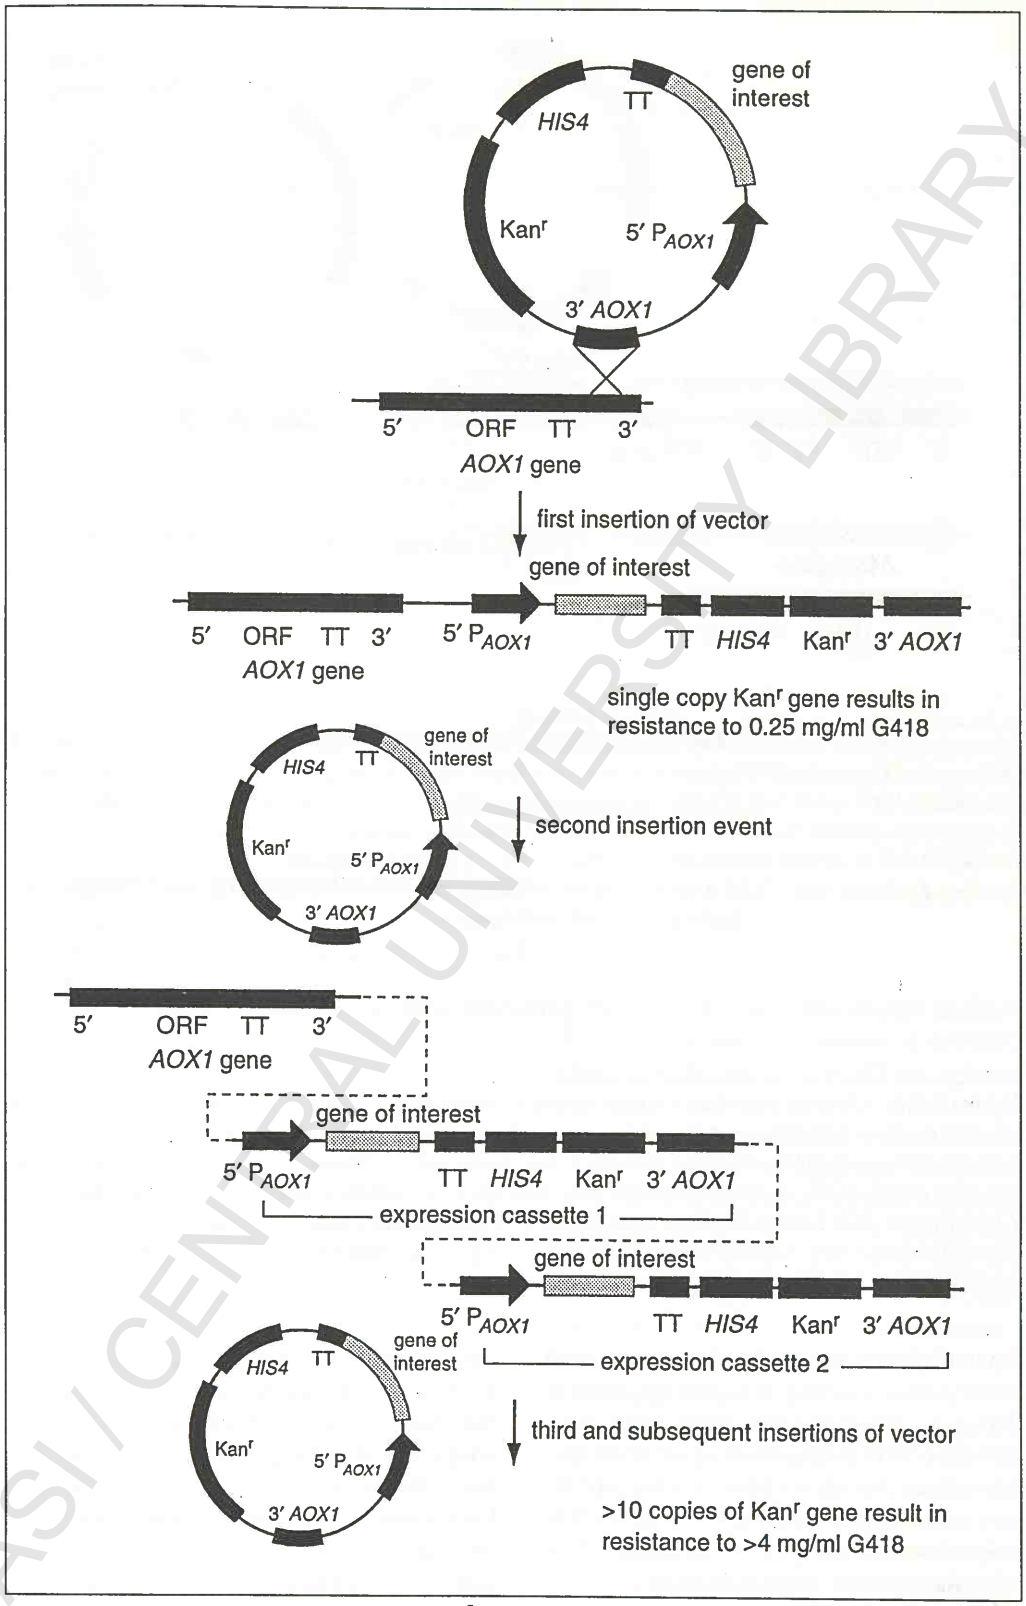

Figure 5.7.6 Multiple insertions with a Kan^r-containing plasmid. Multiple insertions of an expression plasmid 3′ to an otherwise intact *AOX1* locus can result from multimer formation prior to a single insertion event or from multiple sequential insertion events at the same locus. These events can also occur between the 5′ *AOX1* regions on the plasmid and genome, with the resulting insertions 5′ to an intact *AOX1* locus. Each expression cassette introduces a copy of the bacterial Kan^r gene, which confers resistance to G418; multiple copies make recombinant strains hyperresistant to G418, which phenotypically identifies strains carrying multiple copies of the expression cassette. Abbreviations: ORF, open reading frame; TT, transcriptional termination sequence.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

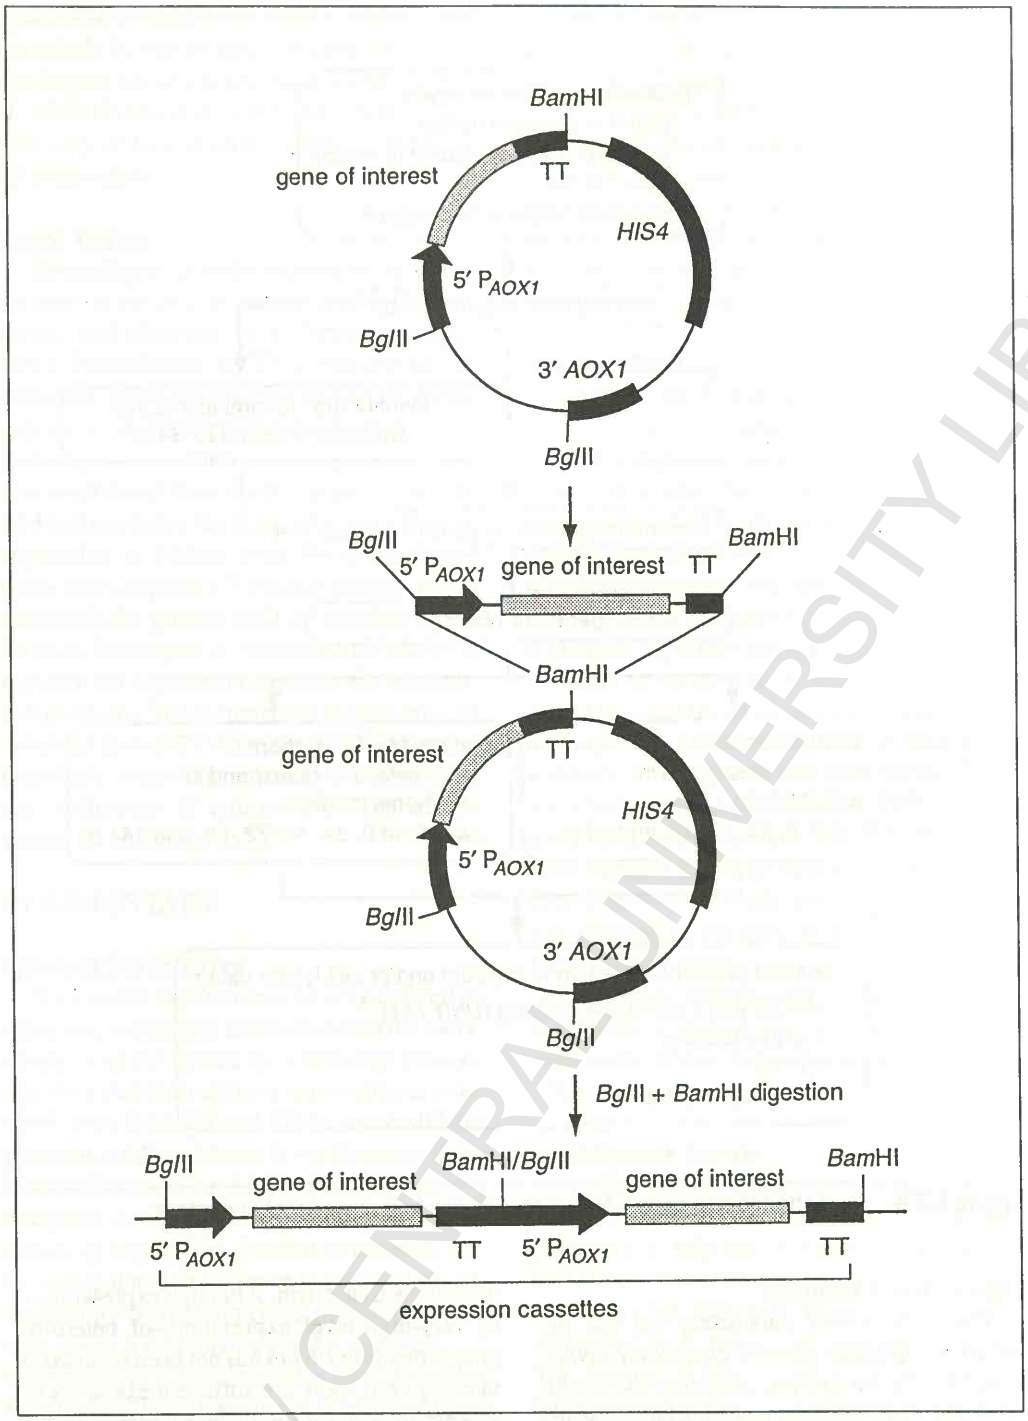

Figure 5.7.7 In vitro multimer formation. By this scheme, multiple copies of P_{AOX1}-gene of interest are ligated together in a plasmid in vitro, and linked to a single *HIS4* gene in an expression cassette. Transformation of *Pichia* with these in vitro–formed multimers is used as a tool to increase the frequency with which multiple-copy expression cassette recombinant strains are generated. Abbreviations: OEF, open reading frame; TT, transcriptional termination sequence.

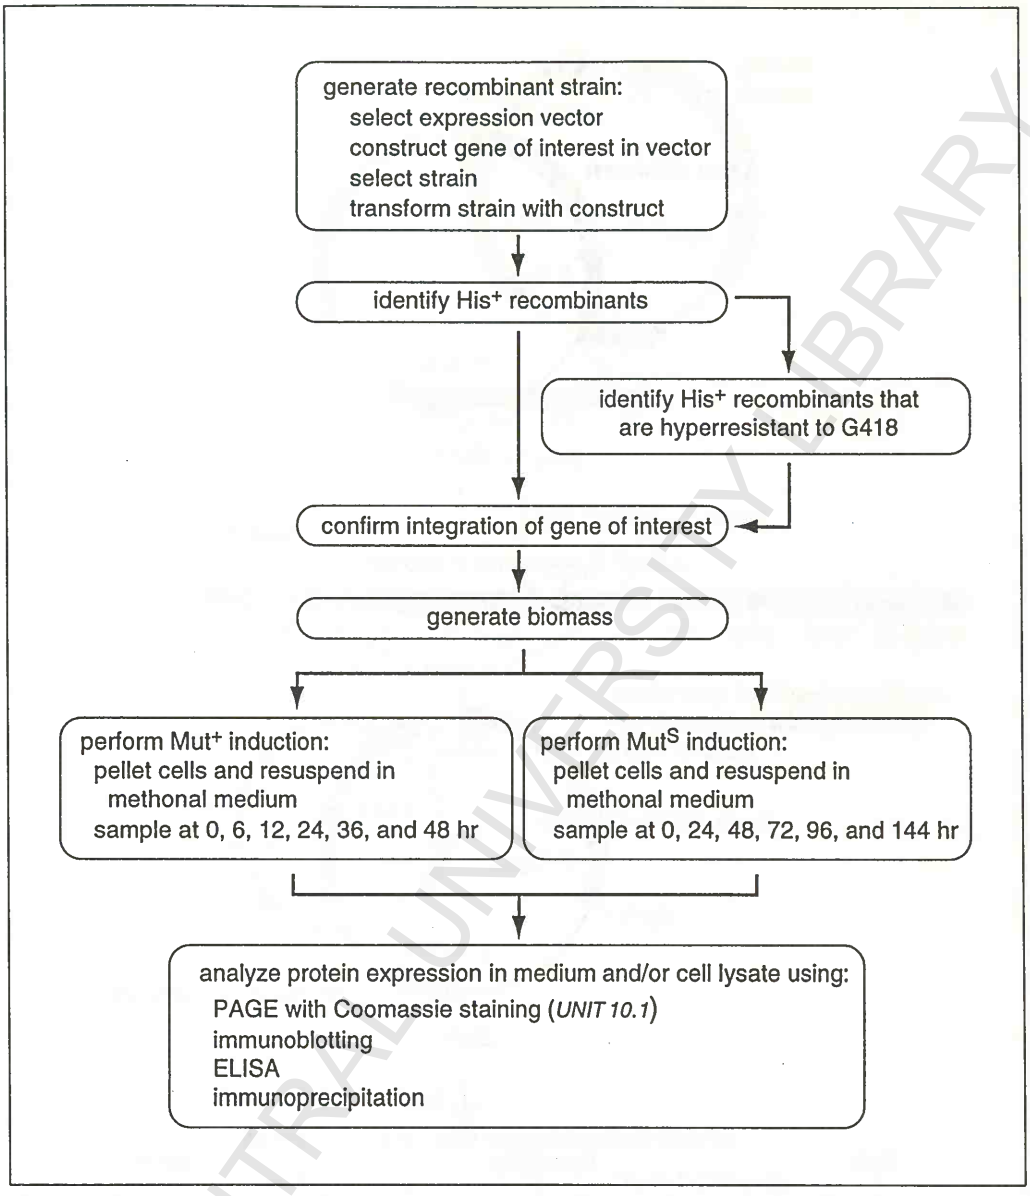
S. cerevisiae core oligosaccharides have terminal α1-3 glycan linkages, whereas *P. pastoris* does not. Furthermore, it is believed that the α1-3 glycan linkages of *S. cerevisiae* are primarily responsible for the hyperantigenic nature of glycosylated proteins from *S. cerevisiae* that makes them particularly unsuitable for therapeutic use. Although not yet proven, this is predicted to be less of a problem for glycoproteins generated in *P. pastoris*, because their glycoprotein structure may resemble that of higher eukaryotes (Cregg et al., 1993).

PSU IACS CENTRAL UNIVERSITY LIBRARY



generate recombinant strain:
select expression vector
construct gene of interest in vector
select strain
transform strain with construct
identify His+ recombinants
identify His+ recombinants that are hyperresistant to G418
confirm integration of gene of interest
generate biomass
perform Mut+ induction:
pellet cells and resuspend in methonal medium
sample at 0, 6, 12, 24, 36, and 48 hr
perform MutS induction:
pellet cells and resuspend in methonal medium
sample at 0, 24, 48, 72, 96, and 144 hr
analyze protein expression in medium and/or cell lysate using:
PAGE with Coomassie staining (UNIT 10.1)
immunoblotting
ELISA
immunoprecipitation

Figure 5.7.8 Flow chart for the generation of recombinant strains of *Pichia pastoris*.

Expression Examples

There are several parameters that can be varied to optimize protein expression levels using the *Pichia* system, including the strain (e.g., protease-deficient strains, Mut$^+$ or Mut^S recombinant strains), intracellular or secreted expression, and flask or fermenter format. Table 5.7.1 lists published examples of heterologous protein expression in *Pichia*. Unpublished examples of proteins expressed in *Pichia* include MHC class II, shark cytochrome p450, muscle kinase, human serum proteins, maize heat shock protein, α-glycosidase, diphenol oxidase, porcine cytokines, antibody heavy and light chains, lysoxygenase, cytochrome *c* reductase, spinach glycolate oxidase, oncostatin M, lactoferrin, bovine rhodopsin, and transmembrane transferrin. Although expression—or very-high-level expression—of heterologous proteins in *Pichia* has not been successful in every case, there are sufficient examples of success to warrant inclusion of *Pichia* in the standard expression repertoire. In addition to the well-publicized examples of high-level expression (Tschopp et al., 1987a; Clare et al., 1991a; Barr et al., 1992), there are several examples that demonstrate *Pichia*'s behavior as a eukaryote capable of correct post-translational processing, including expression of correctly folded heterologous proteins that contain many disulfide bonds (White et al., 1994), proteins that are active when expressed in *Pichia* but not when expressed in *E. coli* (Yamada et al., 1994; Jenkins and Fayer, 1995; Steinlein

RCUIAS CENTRAL UNIVERSITY LIBRARY

et al., 1995; Vozza et al., 1995), and proteins for which *Pichia* properly recognized the native higher eukaryote secretion signal (Barr et al., 1992; Ridder et al., 1995). Levels of expression vary widely, as do the optimal conditions for expression.

Legal Issues

Heterologous protein expression in *Pichia pastoris* is covered by issued patents that are owned and administered by Research Corporation Technologies (RCT). Invitrogen has the exclusive rights for the distribution of *Pichia* expression technology. The *Pichia* expression system (strains, vectors, and reagents) is available to all researchers simply by purchasing the *Pichia* Expression Kit from Invitrogen. Protein expression in *Pichia*, even for research purposes only, requires a "research license" that is automatically granted with the purchase of the kit from Invitrogen. A "commercial license" is required for expression intended for commercial purposes. The commercial license must be obtained from RCT after the kit is purchased. Questions regarding commercial licenses or the definition of commercial application should be addressed to RCT.

COMMENTARY

Critical Parameters

Successful expression—loosely defined as achieving expression levels that meet the users' needs—can be viewed as a two-step process. The first step is to achieve expression at some level, even if suboptimal. Often successful expression is fully achieved in the first step. If the levels of expression obtained initially are not adequate, however, the second step is optimization of expression. Several parameters can be manipulated to optimize expression levels, including (1) expression as an intracellular protein versus a protein targeted for secretion; (2) expression in a Mut^+ versus a Mut^S recombinant strain; (3) expression in a wild-type versus a protease-deficient mutant; (4) expression in recombinant strains with multiple copies of expression cassettes; and (5) optimization of medium conditions, including specific components (i.e., MM versus BMMY), pH, and expression scale (i.e., flasks versus fermentation). Tools have been developed that allow the researcher to manipulate these parameters and optimize expression. It is essential to keep optimization steps in mind when planning the initial expression experiments.

Other critical tools required for success include good, well-defined methods to unambiguously detect heterologous protein expression. Simple visualization via polyacrylamide gel electrophoresis (PAGE; *UNIT 10.1*) with Coomassie or silver staining (*UNIT 10.5*) is ideal, but other, more sensitive tools—such as antibodies for immunoblots, ELISAs, or immunoprecipitations, or assays for an activity associated with the protein being expressed—are also very useful.

Troubleshooting

Although the *Pichia pastoris* system is easy to use, it requires a number of media that may include components and procedures that are new to some labs. The proper recipes and components should be obtained and the media should be prepared well in advance of beginning the experiments (see *UNIT 5.8*). All the media are very stable and have long shelf lives, so it is feasible to prepare them in advance.

There are several methods to transform *P. pastoris* (Ausubel et al., 1995, Chapter 13), although the spheroplast and electroporation methods are probably the most commonly used. Spheroplast transformation is a relatively straightforward procedure, but it may be the most difficult aspect for first-time users of the system to master. Gentle handling of the cells and meticulous attention to the protocol are required for success.

Most other problems that are likely to arise in expression using *P. pastoris* involve protein expression levels, and are outlined in Table 5.7.5.

Anticipated Results

As the number of expressed proteins in *P. pastoris* increases, more information is being generated to help define routes to successful expression. Based on available data, there is an ~50% to 75% chance of expressing a protein of interest in *P. pastoris* at reasonable levels. The biggest hurdle seems to be generating initial success—that is, expression of the protein at any level. After success at this stage, there are many well-defined parameters that can be manipulated to achieve optimization of expression, and it is often at this stage that acceptable levels of expression are achieved. Although there have been relatively few instances of expression of ≥10 g/liter, there have been many cases of expression in the ≥1 g/liter range, ranking the *P. pastoris* expression system as one of the most productive eukaryotic expression systems available. Likewise, there are several proteins that have been successfully

EMORY UNIVERSITY LIBRARY

Table 5.7.5 Troubleshooting Guide for Failure to Obtain Heterologous Protein

Possible cause of failure	Solution
Expression cassette not present	Demonstrate that recombinant strain contains the gene of interest by PCR or Southern blot hybridization
No transcription	Check for mRNA by RT-PCR or northern blot hybridization; check for AT-rich regions that may be functioning as transcription termination sites within coding region of expressed gene (see Scorer et al., 1993)
No translation of mRNA	Check sequence for possible secondary structure in 5′ untranslated region of mRNA Check codon usage and initiation context for gene of interest
Protein instability	Use protease-deficient strain(s) to prevent proteolysis Change medium or pH medium to optimal for protein
Secretion problem: incomplete secretion, retained in secretory pathway, secreted protein improperly processed, improper modification	Check cell pellet for protein Determine apparent MW of protein
Expression too low	Increase copy number of gene of interest by using pPIC3K, pPIC9K, or pAO815; or scale up fermentation
Expressed protein is deleterious to cells	Examine at earlier time points

expressed in *P. pastoris* following a complete lack of success in baculovirus or *S. cerevisiae*, making the *P. pastoris* system an important alternative in the protein expression toolbox.

Time Considerations

Numerous media are needed for recombinant strain generation and protein expression (Table 5.7.3); medium preparation takes about ½ day and should be completed at least 1 day prior to starting the transformation. The transformation procedure takes ~4 hr with an overnight culture inoculated the day before. It takes 4 to 6 days for prototrophic transformants (e.g., His^+) to form colonies. Screening of transformants to distinguish the His^+ Mut^+ from the His^+ Mut^S takes an additional 3 days. Genomic DNA preps to generate template DNA for PCR analysis and PCR analysis itself can be completed in 1 day. Purification of mRNA for RT-PCR or northern analysis takes ~1 day.

For protein expression experiments in flasks, growth of cultures in glycerol medium to generate biomass takes 1 to 2 days. Methanol induction and a time-course study of protein expression goes from 6 hr to 2 days postinduction for Mut^+ recombinant strains and 1 to 6 days for Mut^S recombinant strains. Analysis of expression by PAGE (*UNIT 10.1*), immunoblotting, ELISA, or specific assay usually requires one additional day.

The total elapsed time from the first transformation to the first protein analysis is ~3 to 4 weeks, with fairly continuous attention required. Commonly, the next phase involves optimization and scale-up once acceptable protein expression levels have been demonstrated. It is reasonable to expect that it will take 6 months from the first transformation to achieving medium- or large-scale production of acceptable levels of heterologous protein expression.

Culture of Yeast for the Production of Heterologous Proteins

This unit describes culture of the yeast strains *Saccharomyces cerevisiae* and *Pichia pastoris* for the production of foreign proteins. The theoretical background to foreign gene expression in yeast is discussed in the previous units (*UNITS 5.6 & 5.7*). General techniques for handling yeast are described in Ausubel et al. (1995), Chapter 13, and will not be covered here.

S. cerevisiae expression systems are generally based on the yeast 2μm plasmid, but they differ in choice of promoter and selectable marker, which affect the culture medium and induction conditions that must be used. Vectors with auxotrophic selection markers must be used in appropriate strains (e.g., *LEU2* plasmids in *leu2* strains), and growth must be in appropriate selective medium, i.e., minimal medium containing all the necessary supplements. Vectors with dominant selectable markers (e.g., $G418^r$) can be used in any host strain and selected in rich medium, giving higher growth rate and cell density. The protocols listed here are for three widely used types of promoter: galactose-regulated (*GAL1*, *GAL7*, *GAL10*; Basic Protocol 1), glucose-repressible (e.g., *ADH2*; Alternate Protocol 1), and constitutive glycolytic (e.g., *PGK* or *GAPDH*; Alternate Protocol 2). Minor variations to each can be made depending on the selection system used. The *P. pastoris* expression system uses integrating vectors with the methanol-regulated *AOX1* promoter and *HIS4* selection marker; although transformants are stable, they are generally grown in minimal selective medium.

In most cases, initial analysis is carried out with protein produced in small-scale (5-ml to 1-liter) cultures, and this may be sufficient in cases where the yield is high. Where larger amounts of protein are required, cultures can be grown to high cell density using fermenters. Methods are described for small-scale *S. cerevisiae* (Basic Protocol 1) and *P. pastoris* cultures (Basic Protocol 2) and also for high-density fermentations with these yeasts (Basic Protocols 3 and 4). High-density (>100 g/liter dry weight) growth of *S. cerevisiae* requires computer-controlled carbon source feeding based on continual monitoring of growth parameters (Wang et al., 1979; Fieschko et al., 1987). The protocol given here applies a much simpler feeding strategy based on calculated feed rates (Basic Protocol 3) and yields cell densities of 10 to 30 g/liter (Aiba et al., 1976; Hsieh et al., 1988; Bock Gu et al., 1989). In contrast, with *P. pastoris*, it is simple to obtain extremely high-density cultures (e.g., 130 g/liter) using basic fermenter equipment (Basic Protocol 4). Finally, Support Protocol 1 describes small-scale preparation of protein extracts.

NOTE: All solutions and equipment coming into contact with cells must be sterile, and proper sterile technique should be used accordingly.

SMALL-SCALE EXPRESSION USING *S. CEREVISIAE* GALACTOSE-REGULATED VECTORS

BASIC PROTOCOL 1

Galactose-regulated (*GAL*) promoters are induced >1000-fold by addition of galactose but are strongly repressed by glucose, so that in glucose-grown cultures maximal induction can be achieved only following depletion of glucose. For rapid induction, cells can be grown using a nonrepressing carbon source (e.g., raffinose), then induced by direct addition of galactose. First, saturated overnight starter cultures are prepared, and these are used to inoculate fresh medium. These secondary cultures are grown for two doublings (4 to 5 hr including growth lag) to late exponential phase, then induced by direct addition of galactose. Cells are then harvested by centrifugation and may be stored at –70°C as dry pellets or disrupted immediately, using glass beads, to prepare a total protein extract.

BOSTON UNIVERSITY LIBRARY

With either very stable vectors, or vectors having dominant selectable markers, growth and induction can be carried out in rich medium to maximize cell density. Where the plasmid requires auxotrophic selection, minimal selective medium must be used at least for the starter culture, although the induction itself can still usually be carried out in rich medium. The protocol described below is applicable to culture volumes of 5 to 1000 ml.

Materials

YP broth (see recipe) containing 2% (w/v) raffinose *or* YNB medium (see recipe) for auxotrophic selection
50 mg/ml G418 (100×) or supplements for auxotrophic selection, as required
Saccharomyces cerevisiae transformed with a galactose-regulated expression vector and plated on selective medium (see *UNIT 5.6* and Ausubel et al., 1995, Chapter 13)
20% (w/v) galactose (filter sterilize and store at room temperature)
H_2O, sterile

Plastic 25-ml universal containers, sterile (e.g., Nunc)
Heraeus omnifuge centrifuge and 2250 rotor (or equivalent)
15-ml polypropylene snap-top tubes
Centricon concentrator (Amicon; also see *UNIT 4.4*)

1. Place 10 ml YP broth containing 2% raffinose in a sterile 25-ml universal container and inoculate with cells of a single colony of transformed *S. cerevisiae*. Incubate overnight at 30°C with shaking.

   As expression levels may vary between individual transformants, it may be advisable to test several when looking for optimal yield. For vectors with G418-resistance markers, add G418 (0.5 mg/ml final) to the raffinose preinduction medium. For unstable vectors with auxotrophic markers, use YNB medium (see recipe) with 2% raffinose and the appropriate supplements (cell density will be up to 5-fold lower).

   Glucose can be used in place of raffinose in the preinduction growth stages, especially where it is necessary to maintain tight repression of expression, e.g., in expressing toxic proteins. However, excess glucose must be removed by centrifuging and washing the cells in sterile saline prior to resuspending them in induction medium. For glucose-grown cultures, induction will have a several-hour lag period, during which the glucose is exhausted.

2. Measure the A_{600}.

   The A_{600} of an overnight culture should be ~5.0.

3. Dilute the overnight culture into 10 ml YP broth containing 2% raffinose to an A_{600} of 0.25 (typically a 20-fold dilution). Incubate at 30°C with shaking until the culture density reaches an A_{600} of ~1.0 (4 to 5 hr).

4. Add 1 ml of 20% galactose to induce the culture. Incubate 8 to 24 hr (e.g., overnight) with shaking at 30°C.

5. Measure the A_{600} of the culture.

   The A_{600} of the induced cultures should be 10 to 15.

6a. *For intracellular protein expression:* Harvest the cells by centrifuging 5 min at 2000 × *g*, 4°C. Resuspend the cell pellet in 10 ml water, transfer to a 15-ml snap-top tube, and centrifuge again as before. Remove excess water from the pellet. Store at –70°C.

6b. *For secreted protein expression:* Harvest the cells by centrifuging 5 min at 2000 × *g*, 4°C. Collect the medium (supernatant) and concentrate proteins in the medium by

CSU IASI / SENTRAL UNIVERSITY LIBRARY

ultrafiltration using a Centricon concentrator (Amicon). Store the protein concentrate at –70°C. Retain the cell pellet for analysis.

Several secreted proteins have been found to accumulate to lower levels in minimal medium than in rich medium. Yields in minimal medium have been improved by adding Casamino acids (see recipe) or by buffering to pH 6.0 using potassium phosphate (unbuffered media will reach pH ~4).

To concentrate secreted proteins further, concentrate the cells 20-fold by centrifugation prior to induction.

EXPRESSION USING GLUCOSE-REPRESSIBLE *ADH2* VECTORS

ALTERNATE PROTOCOL 1

The *ADH2* promoter is repressed 100-fold by glucose. To maintain repression, cells must always be grown in excess glucose—e.g., 8% (w/v)—because normal concentrations (e.g., 2%) can become depleted. It is also preferable to store transformants on plates containing 8% glucose. Inductions can be carried out by first growing cells in medium containing excess glucose, then inducing by changing to fresh medium containing a nonfermentable carbon source such as raffinose.

Additional Materials (also see Basic Protocol 1)

YP broth (see recipe) containing 8% (w/v) glucose
Saccharomyces cerevisiae transformed with a glucose-repressible *ADH2* expression vector and plated on selective medium (see UNIT 5.6 and Ausubel et al., 1995, Chapter 13)
YP broth (see recipe) containing either 2% (w/v) raffinose and 2% (v/v) ethanol *or* 1% (w/v) glucose

100-ml Erlenmeyer flask, sterile
Diastix glucose test strips (Bayer Diagnostics; optional)

1. Prepare a 10-ml exponential phase culture of the *S. cerevisiae* transformant in YP broth containing 8% glucose (see Basic Protocol 1, steps 1 to 3).

   Depending on the vector characteristics, selective medium may need to be used, as in Basic Protocol 1.

2. Harvest the cells by centrifuging 5 min at 2000 × *g*, 20°C. Resuspend the pellet in 10 ml sterile water.

3. Centrifuge again as in step 3 and resuspend the pellet in 10 ml YP broth containing 2% raffinose/2% ethanol.

4. Incubate 8 to 24 hr (e.g., overnight) at 30°C under conditions of maximum aeration (e.g., by incubating in a 100-ml Erlenmeyer flask with vigorous agitation).

   Induction starts after a lag of several hours.

   As an alternative to steps 3 and 4, use the overnight starter culture in 8% glucose to inoculate YP broth containing 1% glucose to a starting A_{600} of 0.05 (typically a 100-fold dilution). Incubate 18 to 24 hr at 30°C with vigorous aeration. Monitor glucose depletion using Diastix glucose test strips if possible.

5. Measure the A_{600}.

6. Harvest the cells by centrifuging 5 min at 2000 × *g*, 4°C.

7. Analyze the cell pellet for proteins expressed intracellularly and analyze the cell pellet and the medium (supernatant) for secreted proteins.

BOULDER / CENTRAL UNIVERSITY LIBRARY

ALTERNATE PROTOCOL 2

EXPRESSION USING VECTORS WITH GLYCOLYTIC GENE PROMOTERS

A number of commonly used expression vectors have constitutive promoters from glycolytic genes (e.g., *PGK*, *GAPDH*, and *ADH1*). Because instability problems are more frequent with constitutive vectors, it is recommended that selective media be used throughout.

Materials (also see Basic Protocol 1)

YNB medium (see recipe) containing 2% (w/v) glucose and the required supplements

Saccharomyces cerevisiae transformed with an expression vector containing a glycolytic gene promotor and plated on selective medium (see *UNIT 5.6* and Ausubel et al., 1995, Chapter 13)

1. Prepare an overnight starter culture of the *S. cerevisiae* transformant in YNB medium containing 2% glucose and required supplements (see Basic Protocol, step 1).

   Doubling time for the transformed strain will usually be longer than for the untransformed strain. Constitutive high-level expression using vectors that contain glycolytic gene promotors causes a metabolic burden on the cell that usually results in reduced growth rates. The degree of the effect will depend on the gene expressed, but doubling times may increase to 3 or 4 hr, or greater in extreme cases. Very long doubling times are diagnostic of toxicity, and indicate that a regulated vector should be used.

2. Measure the A_{600}.

   The A_{600} of the overnight culture should be 5.

3. Dilute the overnight culture into 10 ml fresh supplemented YNB medium to an A_{600} of 0.0025.

   Using medium with a higher glucose concentration—e.g., 8% (w/v)—may improve expression levels, because glycolytic promoters are partly glucose-inducible.

4. Incubate at 30°C with shaking until the A_{600} reaches 0.25 to 0.5—18 to 24 hr, depending on the foreign protein.

5. Harvest the cells for analysis by centrifuging 5 min at 2000 × *g*, 4°C.

6. Analyze the cell pellet for proteins expressed intracellularly and analyze the cell pellet and the medium (supernatant) for secreted proteins.

BASIC PROTOCOL 2

SMALL-SCALE EXPRESSION IN *PICHIA PASTORIS*

Small-scale cultures of *Pichia pastoris* are used for the initial analysis of expressed proteins and for monitoring established expression strains. As different transformants may vary widely in product yield, it may be necessary to screen a significant number (see Critical Parameters and *UNIT 5.7*). Aeration is a key consideration because the efficiency of induction is reduced when oxygen is limited. To avoid this, incubate with vigorous shaking, keep the culture volume to a minimum (e.g., 5 to 10 ml) and use large flasks (e.g., >100 ml, preferably baffled) with loose or permeable covers. Some evaporation may occur, and during extended inductions (>1 day) it may be necessary to add further aliquots of methanol. The optimal induction period may vary for different proteins, and it is recommended that a time course be carried out to maximize yields.

CSU IAS CENTRAL UNIVERSITY LIBRARY

Materials

YNB medium (see recipe) containing 2% (w/v) glycerol
Pichia pastoris transformed with an expression vector and plated on selective medium (see *UNIT 5.7* and Ausubel et al., 1995, Chapter 13)
0.002 mg/ml biotin (500×; filter sterilize and store <1 year at 4°C)
H_2O, sterile
YNB medium (see recipe) containing 1% (v/v) methanol

Plastic 25-ml universal containers, sterile
Heraeus omnifuge centrifuge and 2250 rotor (or equivalent)
100-ml Erlenmeyer flasks, sterile
15-ml polypropylene snap-top tubes

1. Place 10 ml YNB broth containing 2% glycerol in a sterile 25-ml universal container and inoculate with cells of a single colony of transformed *P. pastoris*. Incubate overnight at 30°C with shaking.

2. Measure the A_{600}.

   The A_{600} of the overnight culture should be ~5.

3. Dilute the overnight culture into 10 ml YNB medium containing 2% glycerol to an A_{600} of 0.25. Incubate 6 to 8 hr at 30°C with vigorous shaking to obtain an exponentially growing culture.

4. Collect the cells by centrifuging 5 min at 2000 × *g*, 4°C. Resuspend the cell pellet in 10 ml sterile water.

5. Pellet the cells by centrifuging 5 min at 2000 × *g*, 4°C. Resuspend the cell pellet in 10 ml YNB medium containing 1% (v/v) methanol. Incubate 1 to 5 days at 30°C with maximum aeration (e.g., incubate culture in a 100-ml Erlenmeyer flask with vigorous shaking).

   If inducing >1 day, add an additional 0.5% methanol on the second day. The final density of the culture should be A_{600} = 5 to 10. The concentration of a secreted product in the medium is generally proportional to the density of the culture. Thus, to increase the concentration of a secreted protein, grow a larger culture (e.g., 100 ml) and concentrate the cells prior to the induction by resuspending in 5 ml of the methanol-containing induction medium. In addition, the yield of some secreted proteins may be reduced by extracellular proteases. This can sometimes be ameliorated by altering the composition of the medium, for example by buffering the pH or by adding amino acid–rich supplements such as Casamino acids (see recipe) or peptone (Clare et al., 1991b; Cregg et al., 1993).

6. Collect the cells by centrifuging 5 min at 2000 × *g*, 4°C. Resuspend the cell pellet in 10 ml water. If the expressed protein is secreted, retain the supernatant, concentrating the protein by ultrafiltration (see Basic Protocol 1, step 6b).

7. Transfer the cell suspension to a 15-ml polypropylene snap-top tube. Centrifuge 5 min at 2000 × *g*, 4°C. Remove excess water from the pellet and store the washed cell pellet at –70°C.

8. Analyze the cell pellet for intracellularly expressed protein and analyze the cell pellet and the supernatant for secreted protein.

BCU/ASTON/CLARE UNIVERSITY LIBRARY

LARGE-SCALE EXPRESSION USING *S. CEREVISIAE* GALACTOSE-REGULATED VECTORS

High-density fermentation of *S. cerevisiae* is problematic because the yeast has a limited capacity to metabolize glucose oxidatively; ethanol accumulates, which eventually inhibits its growth to a specific growth rate of 0.2 to 0.25 hr^{-1} (Sonnlietner and Kappeli, 1986). Additionally, glucose concentrations above ~0.1% repress respiration. To prevent the conversion of glucose to ethanol and to maximize biomass, *S. cerevisiae* is grown using a fed-batch process: glucose is slowly fed to the fermenter, the feed rate increasing as the cell density increases, so as to obtain an almost constant growth rate (μ). The growth rate above which ethanol is formed (μ_{crit}), and hence the critical feed rate, are determined by both the strain and the growth medium. Figure 5.8.1 shows the relationship between the growth rate and biomass yield, and the effect of exceeding the μ_{crit} (Pirt, 1985). The following simplified protocol uses calculated feed rates.

Materials

YNB medium (see recipe) containing 1% (w/v) glucose and appropriate supplements
Saccharomyces cerevisiae transformed with a galactose-regulated expression vector and plated on selective medium (see *UNIT 5.6* and Ausubel et al., 1995, Chapter 13)
BSSM fermenter medium (see recipe)
20% (w/v) glucose
20% (w/v) galactose
3 M phosphoric acid
3 M sodium hydroxide
Antifoam (Dow Corning M30 antifoam)

250-ml and 2-liter Erlenmeyer flasks, sterile
Benchtop fermenter, 5-liter total volume, with data logging and MENTOR control system (Life Science Laboratories)
Electronic balance (Mettler) with RS232 communications
Sorvall RC-3B centrifuge and H6000A rotor (or equivalent)

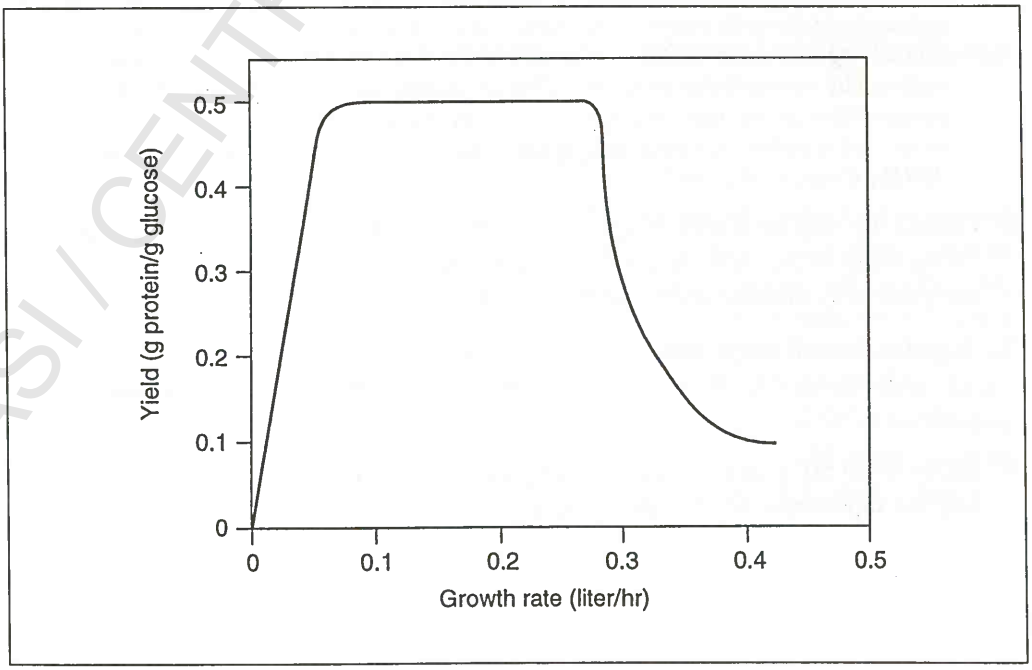

Figure 5.8.1 Effect of growth rate on yield.

EGU IASI / CENTRAL UNIVERSITY LIBRARY

Prepare the cultures

1. Place 50 ml YNB medium containing 1% glucose and supplements in a sterile 250-ml Erlenmeyer flask and inoculate with cells from a single colony of transformed *S. cerevisiae*. Incubate overnight at 30°C with shaking.
2. Measure the A_{600}.

   The A_{600} of the overnight culture should be ~4.0.
3. Dilute 10 ml of the overnight culture into 250 ml YNB medium containing 1% glucose in a 2-liter shaker flask. Incubate 18 to 24 hr at 30°C with shaking (150 rpm).
4. Measure the A_{600}.

   The A_{600} should be ~4.0.

Calculate the feed rate

5. Determine the feed rate for the fermenter using the following equation (see Table 5.8.1 for definitions of terms) for a 20% glucose solution, where $C1 = (X_0 \times V \times \rho)/(Y \times Sf)$.

   $$\text{cumulative weight of feed} = (C1 \times e^{\mu t}) - C1$$

   Based on the approximate values for a 5-liter fermentation protocol given in Table 5.8.1, C1 = 2.7, and the feeding algorithm reduces to:

   $$\text{cumulative weight of feed} = (2.7 \times e^{0.16t}) - 2.7$$
6. Determine the feed profile by calculating the cumulative weight of feed for $t = 1, 2, \ldots, n$ hr. Enter these values into the MENTOR computer system.

Express the protein

7. Place the fermenter reservoir containing 20% glucose feed on an electronic balance linked to MENTOR, which will control the feed rate via a dosing pump.

   The fermentation consists of two phases: a glucose fed-batch phase followed by batch addition of galactose to induce expression.

Table 5.8.1 Variables for Calculating *S. cerevisiae* Feeding Algorithm

Variable	Definition	Value for 5-liter protocol	Comment
X_o	Biomass in fermenter at start of feeding (g/liter)	0.07	Derived by multiplying the starting A_{600} in the fermenter by 0.22 (assume shaker flask inoculum has $A_{600} = 4$)
V	Working volume of fermenter (liter)	3.5	Maximum working volume
Y	Yield coefficient (g cells per g glucose)	0.45	Theoretical value is 0.5, but a more conservative value of 0.45 is recommended
Sf	Glucose concentration in feedstock (g/liter)	200	—
μ	Target growth rate (hr^{-1})	0.16	Suggested value (see text for optimization)
ρ	Feed density (g/liter)	1000	Approximation is sufficient

BCUIAS / CENTRAL UNIVERSITY LIBRARY

8. Add 2.5 liters BSSM fermentation medium to the fermenter. Then add the culture from step 2 to the fermenter and initiate feeding with 20% glucose. Feed for 28 hr.

Monitor the A_{600} closely during feeding; if the growth rate drops below the target ($\lambda = 0.16\ hr^{-1}$), stop glucose feeding early. The growth rate selected in this protocol serves as a useful starting point for any strain. To optimize the protocol, determine the maximum growth rate (μ_{max}) for the strain in shaker-flask cultures, then calculate the feed rate, setting the desired growth rate at $\lambda = 0.5\mu_{max}$. This should be safely below μ_{crit}; if necessary, increase λ from this value. If the feed rate is too high, glucose or ethanol will be detected in the fermentation and biomass yield will be reduced. The effect of altering λ on the feeding profile is shown in Figure 5.8.2.

9. Induce the culture by adding 250 ml of 20% galactose. Incubate the culture 24 hr.

If glucose has accumulated, then induction will be delayed for several hours.

Higher expression levels have been reported when 1% (w/v) galactose is pulsed in during the glucose feeding stage, and the glucose feed is then replaced with a galactose feed (Fieschko et al. 1987).

The duration of induction should be optimized by determining the kinetics of product formation. Harvesting shortly before the culture stops growing may help minimize proteolytic degradation of the product. Cells in stationary phase are more resistant to mechanical breakage.

10. Harvest the culture after induction by centrifuging 10 min at 7000 × *g* in a Sorvall RC-3B centrifuge with H6000A rotor.

11. Analyze the cell pellet for intracellularly expressed protein and analyze the cell pellet and the supernatant for secreted protein.

BASIC PROTOCOL 4

LARGE-SCALE EXPRESSION USING *PICHIA PASTORIS*

Optimal expression in *P. pastoris* requires the use of fermenters, which increases both the efficiency of induction and the culture density. The method is simple, requiring only a basic fermenter with monitors and controls for pH, dissolved O_2, stirring speed, temperature, and air flow. Cultures are grown in a defined medium containing glycerol. The pH is maintained by the addition of ammonium hydroxide, which also serves as the nitrogen source. Dissolved O_2 must be maintained at >20% for optimal growth. Fermentations are carried out in three stages: an initial batch growth phase, a glycerol-limited phase during which the culture reaches high cell density, and, finally, a methanol-induction phase of

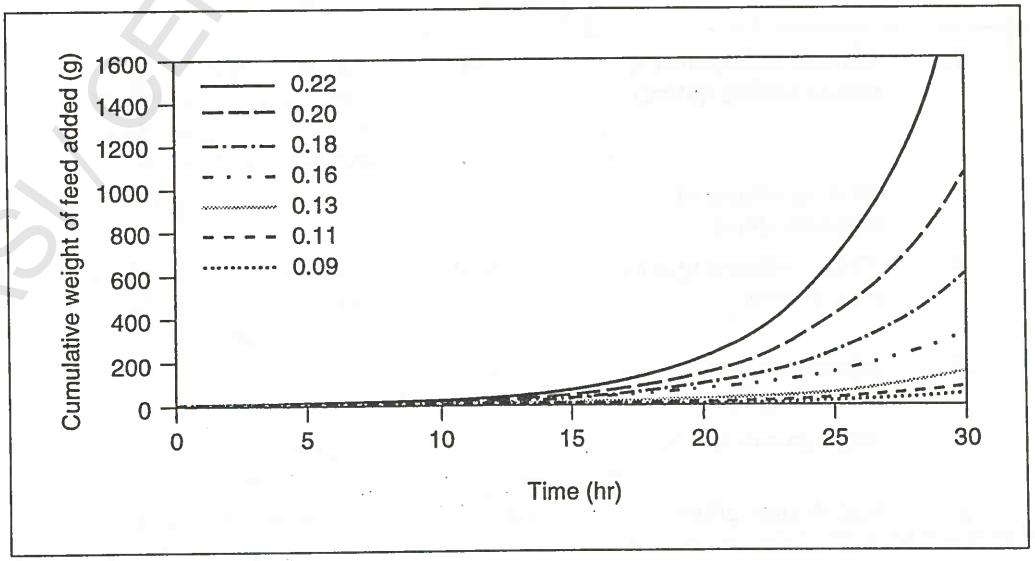

Figure 5.8.2 Effect of growth rate on feed profile.

PCU IASL CENTRAL UNIVERSITY LIBRARY

several days during which product accumulates. The protocol given below is for a 1-liter "bench-top" fermenter, but very similar conditions have been used for cultures up to 240 liters (Cregg et al., 1987).

Materials

YNB medium (see recipe) containing 2% (v/v) glycerol
Pichia pastoris transformed with an expression vector and plated on selective medium (see *UNIT 5.7* and Ausubel et al., 1995, Chapter 13)
5× basal salts solution (see recipe)
PTM_1 solution (see recipe)
Glycerol/PTM_1: 12 ml PTM_1 solution/liter 50% (v/v) glycerol
50% (v/v) ammonium hydroxide
Methanol/PTM_1: 12 ml PTM_1 solution/liter 100% methanol

Fermenter equipped with monitors or controls for pH, temperature, dissolved O_2, airflow, and stirring speed
Erlenmeyer flask, sterile

1. Place 10 to 50 ml YNB medium containing 2% glycerol in an Erlenmeyer flask and inoculate with cells of a single colony of transformed *P. pastoris*. Incubate overnight at 30°C with shaking.
2. Add 1 liter of 5× basal salt solution, 4 ml PTM_1 solution, and 5% (v/v) glycerol to the fermenter and mix well.
3. Add the overnight culture to the fermenter. Incubate at 30°C until the glycerol is exhausted (~24 to 30 hr). Adjust the aeration and agitation to maintain dissolved O_2 at >20%, and maintain the pH at 5.0 with 50% ammonium hydroxide.

   The dissolved O_2 level will begin to rise sharply when the glycerol becomes exhausted.
4. Initiate a limited glycerol/PTM_1 feed at 12 ml/hr and continue for 4 to 24 hr, maintaining pH, temperature, and dissolved O_2.

   During this period the culture should grow to a density of 30 to 100 g dry weight/liter. Cell density can be monitored by measuring A_{600}; 1 A_{600} unit = ~0.33 g/liter, although different spectrophotometers will vary and each should be calibrated individually.

   To achieve optimal yield, the duration of this glycerol-limited phase, and thus the cell density at induction, can be varied depending on the type of product and the Mut phenotype of the host (see UNIT 5.7). Mut^+ strains can be induced at low cell density because they continue to grow during induction. Mut^S strains should be allowed to achieve high density before induction. The yield of secreted proteins may be improved by early induction, allowing secretion to occur during a period of active growth.
5. Induce the culture by replacing the glycerol feed with a methanol/PTM_1 feed at the rate of 1 ml/hr. Gradually increase the methanol feed rate over a period of 6 hr to 6 to 10 ml/hr and continue fermentation for an additional 46 to 92 hr.

   For efficient induction of Mut^+ strains, the aim is to achieve maximal methanol feed rates (after an initial period to adapt the culture to methanol utilization) while maintaining sufficient aeration. If dissolved oxygen levels cannot be maintained >20%, the methanol feed rate should be reduced. This will also prevent accumulation of toxic levels of methanol. To avoid this problem with Mut^S strains, the methanol feed rate should be reduced to 1 ml/hr after 48 hr of induction.

SUPPORT PROTOCOL

SMALL-SCALE PREPARATION OF PROTEIN EXTRACTS

Following induction using one of the previous basic or alternate protocols, protein extracts may be made from the harvested yeast cells either by mechanical disruption or by spheroplasting followed by lysis in hypotonic buffer. A simple mechanical disruption method is described here, in which cells are vortexed in the presence of glass beads. This method can be used for both analytical- (e.g., 10-ml) or preparative-scale cultures; for the latter a Bead Beater (BioSpec Products) may be used. Cells from 10-ml inductions can be disrupted rapidly using glass beads on a vortex mixer with tube rack. For *Pichia pastoris* high-density fermentations of >2 liters, a larger bead mill with efficient cooling is required (Dyno Mill). Although proteases are less of a problem than with *Escherichia coli*, cell breakage should be carried out in the cold, ideally in the presence of protease inhibitors. A typical extraction buffer is given here, but the particular buffer used will depend on the protein being studied and the subsequent analysis or purification to be performed. If the aim is simply to detect a polypeptide by SDS-polyacrylamide gel electrophoresis (*UNIT 10.1*), the composition of the buffer is less important, because the total extract is denatured before analysis.

Materials

Cell pellet from an induced culture of transformed yeast cells
Protein extraction buffer (see recipe), ice-cold
5× protease inhibitor cocktail (see recipe)

15-ml polypropylene snap-top tubes
0.45-mm glass beads, acid washed (see recipe)
Platform vortex mixer (e.g., IKA-Vibrax-VXR with test tube rack)

1. Resuspend the cell pellet from an induced culture of transformed yeast cells in 0.5 ml ice-cold extraction buffer plus 125 µl of 5× protease inhibitor cocktail in a 15-ml polypropylene snap-cap tube.
2. Add glass beads to two-thirds the height of the meniscus. Place the tubes on a platform vortex mixer in a cold room and vortex 10 min at full speed.

   Samples can be vortexed by hand using a vortex mixer in six 30-sec bursts punctuated by 30-sec intervals on ice. Breakage can be checked using a phase-contrast light microscope: intact cells appear bright and broken cells are phase-dark "ghosts." Breakage is most efficient in wide round-bottom tubes. For larger volumes use 30-ml centrifuge tubes or a Bead Beater.
3. Recover the cell extract from the glass beads using a fine-tipped plastic Pasteur pipette. To recover as much of the extract as possible, reextract the beads with 0.5 ml ice-cold extraction buffer.

   Alternatively, centrifuge the cell extract and beads 2 min at 1000 × g, 4°C, through a plastic disposable filter (e.g., Poly-Prep chromatography columns, Bio-Rad). Check that the protein of interest is not retained by the filter.

   For large-scale purification of cytosolic proteins, the preparation may be centrifuged 1 hr at 100,000 × g, 4°C, to pellet membranes.
4. Determine the total protein concentration of the extract using a standard assay (e.g., Bio-Rad protein assay; also see *UNIT 3.4*).

   The yield of total protein from a 10-ml culture grown to A_{600} = 10 is ~10 mg.

PCU IASI / FEDERAL UNIVERSITY LIBRARY

5. If desired, separate insoluble protein by microcentrifuging 15 min at 12,000 × *g*, 4°C. Transfer the soluble protein to a new tube and determine the protein concentration; retain this and the pellet containing insoluble proteins for analysis.

   To determine the proportion of a protein that is soluble, resuspend the insoluble protein pellet in the same volume of buffer as the soluble protein preparation, and analyze equal volumes of total, soluble, and insoluble protein by SDS-PAGE (see UNIT 10.1).

6. Store protein extracts at –20° or –70°C.

   Upon thawing, a precipitate, largely consisting of cell membranes, may appear; this should be dispersed prior to SDS-PAGE (e.g., by pipetting up and down).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Basal salts solution, 5×

Per liter:
42 ml phosphoric acid (0.62 M final)
1.8 g calcium sulfate·$2H_2O$ (10 mM final)
28.6 g potassium sulfate (0.16 M final)
23.4 g magnesium sulfate·$7H_2O$ (10 mM final)
6.5 g potassium hydroxide (0.12 M final)
Autoclave
Store indefinitely at room temperature

BSSM fermenter medium

3.35 g monobasic potassium phosphate (1 mM final)
1.8 g magnesium sulfate·$7H_2O$ (3 mM final)
26.25 g ammonium sulfate (0.08 M final)
2.5 liters distilled water
0.6 ml 0.07 M manganese sulfate·$4H_2O$ (20 µM final)
0.6 ml 0.08 M copper sulfate·$5H_2O$ (20 µM final)
0.6 ml 0.6 mM zinc sulfate·$7H_2O$ (4 µM final)
0.1 ml 33 mM potassium iodide (1 µM final)
0.1 ml 0.39 M sodium molybdate·$2H_2O$ (20 µM final)
0.1 ml 0.08 M ferric chloride·$6H_2O$ (3 µM final)
Place in 5-liter fermenter vessel and autoclave
Add 50 ml vitamin solution (see recipe)

Casamino acids, 10×

Prepare a 20% (w/v) solution of Casamino acids (low-salt, Difco). Autoclave. Store up to 1 year at 4°C.

Glass beads, acid washed

Wash 0.45-mm-diameter glass beads (B. Braun) for 16 hr in concentrated HCl. Rinse thoroughly in distilled water. Bake 16 hr at >150°C. Store indefinitely at room temperature.

BCU FISH CENTRAL UNIVERSITY LIBRARY

Protease inhibitor cocktail, 5×

20 mM EDTA
20 mM EGTA
20 mM PMSF
10 mg/ml pepstatin
10 mg/ml leupeptin
10 mg/ml chymostatin
10 mg/ml antipain
Store in 1-ml aliquots up to 1 year at –20°C

Protein extraction buffer

50 mM Tris·Cl, pH 7.4
100 mM NaCl
2 mM EDTA
Autoclave
Store indefinitely at room temperature
Chill on ice before use

PTM_1 salt solution

Per liter:
6 g cupric sulfate·$5H_2O$ (24 mM final)
0.08 g potassium iodide (0.5 mM final)
3 g manganese sulfate·H_2O (18 mM final)
0.2 g sodium molybdate·$2H_2O$ (0.8 mM final)
0.02 g boric acid (0.3 mM final)
0.5 g cobalt chloride·$6H_2O$ (2 mM final)
20 g zinc chloride (0.15 M final)
65 g ferrous sulfate·$7H_2O$ (0.23 M final)
0.2 g biotin (0.8 mM final)
5 ml sulfuric acid (0.9 M final)
Autoclave
Store indefinitely at room temperature

Vitamin solution

Per 50 ml:
10 mg biotin
65 mg pantothenic acid
100 mg *meso*-inositol
5 mg 4-aminobenzoic acid
65 mg pyridoxine·HCl
50 mg thiamine
50 mg nicotinic acid
Filter sterilize
Store up to 1 year at 4°C

The vitamin solution can also be prepared as a 10× stock.

YNB stock, 10×

Dissolve 6.7 g yeast nitrogen base without amino acids (Difco) in 100 ml distilled water. Filter sterilize with 0.2-μm filter. Store up to 1 year at 4°C.

BCU IASI CENTRAL UNIVERSITY LIBRARY

YNB medium

Add 10× YNB stock (see recipe) and 500× biotin stock to sterile distilled water to give 1× final concentration for basic YNB medium. Add a carbon source (e.g., glucose or raffinose) and nutritional supplements (see Table 5.8.2) according to vector selection requirements. Store up to 1 year at 4°C.

Table 5.8.2 Nutritional Supplements for YNB Medium

Nutrient[a]	Final concentration[b] (mg/liter)
Adenine sulphate	20
L-Arginine·HCl	20
L-Aspartic acid	100
L-Glutamic acid	100
L-Histidine·HCl	20
L-Isoleucine	30
L-Leucine	30
L-Lysine·HCl	30
L-Methionine	20
L-Phenylalanine	50
L-Serine	375

L-Tryptophan	20
L-Tyrosine	30
Uracil	20
Valine	150

[a]Prepare as 100× stock solutions and filter sterilize. Store at 4°C.
[b]Add to filter-sterilized medium.

YP broth

10 g yeast extract
20 g Bacto Peptone
1 liter H_2O
Autoclave
Store up to 1 year at room temperature

COMMENTARY

Background Information

Yeast expression systems have advantages over other commonly used systems for the production of proteins in certain situations (see *UNITS 5.6 & 5.7* and Romanos et al., 1992). Although typical percentage yields of proteins in *Saccharomyces cerevisiae* (1% to 5% of cell protein) are less than those obtained with *Escherichia coli* or baculovirus, the volumetric yield with *S. cerevisiae* may be higher than with the baculovirus system due to the much higher cell density. Depending on the productivity of the strain, shaker-flask inductions, scaled up to 1 liter if necessary, may be sufficient to provide the amount of protein needed. Where a significant amount of protein is required, e.g., >100 mg, fermenters may be used to culture yeast to extremely high density, e.g., 100 g dry weight/liter; this is particularly valuable with secretion, where the concentration of protein in the medium can increase almost proportionately. Because of the technical complexity involved in achieving such densities with *S. cerevisiae*, this unit includes a much simplified protocol using calculated feeding rates, which gives lower cell densities. However, the au-

[c]Scale-up without loss of yield to >4 g/liter.

thors recommend the use of *Pichia pastoris* for high-density fermentation wherever possible.

P. pastoris is an industrial yeast, initially selected for its high-density growth in simple defined media; this organism has also been developed as an expression system (Romanos et al., 1992; Cregg et al., 1993). There are numerous cases in which much higher percentage yields of intracellular proteins have been obtained using *P. pastoris* than using *S. cerevisiae*, often to levels equivalent to those in *E. coli* and baculovirus—e.g., 5% to 40% of cell protein (Sreekrishna et al., 1989; Clare et al., 1991a; Romanos et al., 1991). Table 5.8.3 shows comparative data for two proteins expressed in *E. coli*, baculovirus, *S. cerevisiae*, and *P. pastoris*. *P. pastoris* is also generally more efficient in secreting foreign proteins (Clare et al., 1991b). Moreover, scale-up of *P. pastoris* to high-density fermentations is very simple and can give enormous yields on a volumetric basis. The tight regulation of the *AOX1* promoter means that the growth phase is essentially identical for different protein products, and scale-up to large fermenters does not affect biomass or product yield. Additionally, contrary to the experience with *S. cerevisiae*, an immediate improvement in percentage yield of foreign protein is generally seen on going from shaker flasks to fermenters. This appears to be due at least in part to the high O_2 demand of the organism, which is not satisfied in shaker flasks. For further general information on use of the *P. pastoris* system, consult the instruction manual available from Invitrogen and UNIT 5.7.

Critical Parameters

S. cerevisiae shaker-flask inductions are relatively straightforward, but improvements can be made by testing different host strains, including protease-deficient strains. In *S. cerevisiae* fed-batch fermentations, achieving the correct feed rate is critical; overfeeding, especially in the first few hours, will result in lower cell yield. Because the feed rate in the protocol given here is calculated, it is essential that the density of the inoculum reaches the required level. Another critical factor is dissolved oxygen: levels <30% of saturation affect cell growth, while <10% may affect expression. Increasing the agitation or air-flow rate can increase dissolved oxygen.

The most important factors affecting expression in *P. pastoris* have been discussed in reviews (e.g., Romanos et al., 1992; Cregg et al., 1993; UNIT 5.7). When using *P. pastoris*, selection of the transformant and growth conditions are highly critical. Selection of the transformant is important because *P. pastoris* transformations, especially *Bgl*II transplacements, result in a highly heterogeneous population of transformants. The variables are Mut phenotype (determined by whether or not *AOX1* is disrupted), site of integration, and copy number. For intracellular proteins this usually results in extreme clonal variation in yield between different transformants, dependent mainly on the number of copies of the vector integrated into the chromosome (Sreekrishna et al., 1989; Clare et al., 1991a; Romanos et al., 1991; Scorer et al., 1994). A number of approaches have been used to maximize vector copy number—e.g., screening transformants by DNA dot blot (Romanos et al., 1991) and G418 selection (Scorer et al., 1994). Although it appears that the highest copy numbers result from transplacements using the spheroplast technique, for rapid isolation of near-optimal transformants the authors recommend the much simpler method of G418 selection following electroporation (Scorer et al., 1994).

With secretion of foreign proteins, by contrast, the presence of many copies is sometimes

EDUCATIONAL UNIVERSITY LIBRARY

suboptimal, and the Mut phenotype may have a greater influence on yields; consequently, a significant number of transformants with different copy numbers may need to be tested for maximum yield (Thill et al., 1990; Clare et al., 1991b). An alternative approach is to preselect efficient secretors empirically by micro-scale inductions in 96-well plates (Laroche et al., 1994).

A critical factor during *P. pastoris* growth is its tendency to become oxygen-limited in small-scale inductions, leading to low and variable yields. This effect can be minimized by taking steps to ensure good aeration. However, it is nevertheless a major reason for switching to fermenters as soon as the most efficiently expressing transformants have been identified from small-scale inductions. The change from small-scale to fermenter is usually accompanied by an increase in percentage yield.

A factor that affects *P. pastoris* fermentations is the Mut phenotype, which determines whether or not there is continued growth during the methanol induction phase. Mut^+ strains have a greater tendency to become oxygen-limited during induction and may give more variable yields in small-scale inductions. The methanol feeding rate will be different for Mut^+ and Mut^S strains because the latter can be poisoned by excess methanol feeding.

Troubleshooting

Problems in expression can arise at numerous stages from vector stability through to protein turnover. The following problems are among the most common: (1) genetic instability of the transformed yeast strain, particularly on scale-up; (2) inability to produce some proteins because of their high toxicity; (3) failure to express AT-rich genes due to premature transcriptional termination; (4) inefficient secretion of some larger (>30 kDa) proteins; (5) proteolysis of secreted proteins; and (6) inappropriate glycosylation of mammalian glycoproteins. These problems have been discussed in previous reviews (e.g., Romanos et al., 1992; *UNITS 5.6 & 5.7*), and this section will concentrate on those problems related purely to strain stability and growth conditions.

In *S. cerevisiae*, low yields of foreign proteins may arise because of reduced copy number, rearrangement, or mutation of the vector, most frequently during the constitutive expression of toxic proteins. The solution to most of these problems is simply to use a tightly regulated promoter—e.g., a *GAL* promoter or the *P. pastoris AOX1* promoter—to reduce selection pressure during the growth phase of the culture. It is also good practice to always prepare banks of −70°C glycerol stocks of selected transformants before the start of a project, so that the starting point of each culture is the same. However, extreme product toxicity can be an intractable problem, and it may then be more profitable to try a transient expression system, such as baculovirus.

In *P. pastoris*, a common problem is proteolysis of secreted proteins (reviewed in Cregg et al., 1993). The problem may occur in shaker flasks but is exacerbated in high-density fermenter cultures, possibly due to the higher concentration of proteases and the different medium used. A number of strategies have been used successfully to overcome proteolysis: adding peptide supplements (peptone or Casamino acids), buffering the medium to pH 3 or 6, or using a *pep4* protease-deficient strain.

Anticipated Results

Yields of intracellular proteins from *S. cerevisiae* are usually in the range of 0.5% to 5% of total cell protein, or 1.5 to 15 mg/liter/A_{600} unit (15 to 150 mg/liter for typical culture densities in YP medium). Many small non-glycosylated polypeptides are efficiently secreted and may reach levels of 10 mg/liter/A_{600} unit in the culture supernatant. Larger proteins (>25 kDa) are secreted far less predictably, some efficiently and some poorly. The cell density at the end of the fed-batch phase of *S. cerevisiae* fermentations should reach at least $A_{600} = 20$ (4.0 g/liter) and $A_{600} = 40$ (8 g/liter) at harvest. Using this protocol with minor modifications, such as the use of complex medium, cell densities in excess of 30 g/liter have been reported (Hsieh et al., 1988). Yields are highly strain- and protein-specific. Typical yields with this protocol are ~0.3 g/liter for intracellular products and ~100 mg/liter for extracellular products.

P. pastoris frequently yields intracellular products at 5% to 30% of cell protein. Cell density reaches 130 g dry weight/liter in the fermenter, of which >30% is protein; this is equivalent to at least 2 to 12 g/liter of product. As with *S. cerevisiae*, yields of secreted proteins are less predictable but frequently reach several hundred mg/liter at high cell density, and may constitute the only major protein in the culture medium. It is recommended that positive control strains—e.g., a strain expressing β-galactosidase—be used to ensure that the

BOULDER CENTRAL LIBRARY

induction conditions are optimal; control strains for *P. pastoris* can be obtained from Invitrogen.

Time Considerations

Small-scale *S. cerevisiae* inductions take a total of 2 days from inoculation of the starter culture to harvesting of the induced cells. Several inductions (e.g., 24) can be carried out at a time. *P. pastoris* inductions are generally carried out for 2 to 5 days; therefore, the procedure takes 3 to 6 days from start to finish, depending on the optimal length of induction for the particular protein.

S. cerevisiae fermentations typically take 4 days from start to finish: 2 days for inoculum development, 1 day for biomass accumulation on glucose, and ~1 day for galactose induction. *P. pastoris* 1-liter fermentations typically take 5 days from start to finish: 1 day to produce a starter inoculum, 2 days for biomass accumulation on glycerol, and up to 2 days for methanol induction. Some workers have reported that Mut^S inductions require a longer period, but this has not been the authors' experience. Half a day is required after the fermenter run to harvest and wash cells and to clean the fermenter.

Overview of Protein Expression by Mammalian Cells

In recent years, mammalian cells have been used in the production of recombinant proteins, antibodies, viruses, viral-subunit proteins, and gene-therapy vectors. In addition to being used in commercial biotechnology, mammalian cell systems have served as a means for examining fundamental aspects of gene replication, transcription, translation, and post-translational protein processing.

The availability of transformable cell lines, along with viral and plasmid-based mammalian-cell vector systems, has provided tools through which important aspects of mammalian gene function can be investigated. The following are typical uses for mammalian expression systems:

1. verification of a cloned gene product;
2. analysis of the effects of protein expression on cell physiology;
3. production and isolation of genes from cDNA libraries;
4. production of correctly folded and glycosylated proteins for assessment of biological activity in both in vitro and in vivo systems;
5. production of suitable quantities of proteins and glycoproteins for structural characterization of protein and carbohydrate moieties;
6. production of important clinically active viral surface antigens—e.g., prehepatitis B virus surface antigen (preS2 HBVsAg)—as well as therapeutic proteins—e.g., β-interferon, tissue plasminogen activator (tPA), erythropoietin (EPO), and Factor VIII; and
7. production of monoclonal antibodies.

Important features of mammalian cells include their ability to perform post-translational modifications and to secrete glycoproteins that are correctly folded and contain complex antennary oligosaccharides with terminal sialic acid. These covalent modifications may modulate the clinical efficacy of the protein (e.g., circulatory half-life and biospecificity) or result in properties that are of interest for biochemical characterization—e.g., with respect to structural stabilization, functional groups, and biological role. Mammalian-produced proteins are quality-controlled through a process whereby the progress of incompletely folded, misassembled, and unassembled proteins into the secretory pathway is selectively inhibited (Hurtley and Helenius, 1989). The correctly processed material progresses and is generally secreted as fully active protein. Another important feature of mammalian cell expression has been the ability to provide proteins bearing sialyl glycoforms closely resembling glycoproteins produced by humans. In contrast, *E. coli* does not possess any glycosylation machinery and yeast tends to produce hypermannose-type glycosylation. The yeast-produced glycoproteins are rapidly cleared from the circulation by the liver and also may induce adverse immunogenic responses in humans.

The post-translational modifications performed by mammalian cells include the proteolytic processing of the propeptide (Neurath, 1989) as well as glycosylation and carbohydrate trimming (Hirschberg and Snider, 1987). Other modifications may include γ carboxylation of glutamic acid residues (Suttie, 1985; Kaufman et al., 1986a); hydroxylation of aspartic acid and asparagine residues (Stenflo, 1989); sulfation of tyrosine residues (Baeuerle and Huttner, 1987); phosphorylation of proteins through cell receptor–protein interaction (Myers et al., 1994); fatty acid acylation (McIlhinney, 1990); and correct assembly of multimeric proteins. In contrast to what happens in mammalian cells, the production of intracellular recombinant proteins in *E. coli* leads to accumulation of the protein in reduced form, often as insoluble refractile bodies requiring subsequent denaturation and refolding.

This unit will briefly review the stages involved in protein production in mammalian cells using the stable-expression approach as outlined in Figure 5.9.1. Discussion will include choice of cell type, transfection of the host cells, methods for selection and amplification of transformants, and growth of cells at appropriate scale for protein production. Since post-transcriptional modification and intracellular protein transportation are important features of recombinant-protein production in mammalian cells, some description of these mechanisms is included.

CHOICE OF MAMMALIAN CELL HOST

Although a variety of mammalian cell hosts are available for protein production, only a small number have emerged as systems of choice for production of proteins to be used clinically. The most common of these cell hosts

BOSTON CENTRAL UNIVERSITY LIBRARY

are summarized in Table 5.9.1. The narrowing down of choices is largely due to the need for cell lines that: (1) are capable of continuous growth; (2) can be grown in suspension (in bioreactors); (3) have low risk of adventitious infection by potentially pathogenic viruses; (4) have genetic stability; and (5) can be readily characterized with respect to karyology, morphology, isoenzymes, and gene copy number. The existence of a variety of host-cell systems, the availability of viral or cDNA-based vectors, and the possibility of either stable or transient expression requires that the prospective user define an expression strategy based on ultimate goals. When the researcher's objectives require <1 mg of protein, transient expression in COS-7 cells is the relevant route. Transient expression in the COS-cell and vaccinia systems has been recently reviewed (Moss and Earl, 1991; Aruffo, 1997), and detailed protocols for construction of suitable vectors and protein expression by these systems can be found in those articles.

In transient expression a burst of production occurs in the host cell and is usually accompa-

Table 5.9.1 Common Mammalian Cell Hosts

Cell line	Description	Growth	Utility	Source[a]
Human				
Namalwa	Burkitt's lymphoma–transformed lymphoblastoid cell	Large-scale suspension	Production of α interferon (e.g., by Burroughs Wellcome)	ATCC #CRL-1432
HeLa	Aneuploid cervical carcinoma cell	Small-scale suspension	Production of small quantities of research material (few mg)	ATCC #CCL-2
293	Transformed kidney cell	Small-scale suspension	Production of small quantities of research material (few mg)	ATCC #CCL-1573
WI-38	Human diploid normal embryonic lung cell	Attachment only	Host for virus production	ATCC #CCL-75
MRC-5	Human diploid normal embryonic lung cell	Attachment only	Hardier host for virus production—e.g., hepatitis A	ATCC #CCL-171
HepG2	Liver carcinoma transformed cell	Attachment	Small-scale evaluation of expression—e.g., HBVsAg	ATCC #HB-8065
Rodent				
3T3	Swiss mouse embryo fibroblast	Attachment	Used in testing transforming agents, expression evaluation	ATCC #CCL-92
L-929	Normal connective tissue fibroblasts	Attachment	Small-scale evaluations of expression	ATCC #CCL-1
Myeloma (e.g., NS/O)	Many types	Large-scale suspension	Monoclonal antibody production	ATCC (and commercial sources)
BHK-21	Baby hamster kidney cell	Large-scale suspension	Host for virus production or for stable gene integration	ATCC #CCL-10
CHO-K1	Chinese hamster ovary cell	Large-scale suspension	Used with glutamine synthetase system	ATCC #CCL-61
CHO DG44	Chinese hamster ovary cell	Large-scale suspension	Host for DHFR coamplification	L. Chasin[b]
CHO DXB11	Chinese hamster ovary cell	Large-scale suspension	Preferred host for DHFR coamplification	L. Chasin[b]
Monkey				
COS-7	Transformed African green monkey kidney cell	Small-scale attachment	Transient expression host	ATCC #CCL-1651
Vero	Normal African green monkey kidney cell	Large-scale attachment	Production of viruses	ATCC #CCL-81

nied by death and rapid lysis of the cell. This presents the purification scientist with the challenge of fishing out the protein of interest, which may be present at ~5 μg/ml, from a soup of lysed cellular protein, nucleic acids, and viral particles. The yield of product during purification may be low as a result of the low titer and starting purity; however, when only small quantities of protein are required, transient expression in COS cells or the vaccinia system is a quick and suitable system to employ.

For production of larger quantities of protein, stable expression must be used because of the difficulty in scaling up transient expression into a bioreactor system. Stable expression in Chinese hamster ovary (CHO) cells has previously been described (Kingston et al., 1993).

Some cell lines have successfully been used as hosts in production of viruses and useful proteins. These include the human embryonic lung cell line MRC-5 and the normal embryonic cell line WI-38. These cells are attachment growth–dependent and have a finite lifespan of ~50 generations, after which time the cells enter a senescent phase and begin to die.

Cell lines that have undergone transformation by virus or that have experienced alteration of chromosomes can exhibit a capacity for infinite growth as well as an ability to grow in suspension. Examples of such cell lines are HeLa cells from a human cervical cancer and Namalwa cells from a human lymphoma. There has been some reluctance to use these cell lines in production of clinical agents because of the possibility of transfer of tumorigenic agents to the product. For production of larger amounts of recombinant protein, stable expression is required and has been primarily performed in CHO cells, baby hamster kidney (BHK-21) cells, or myeloma cells (e.g., NS/O). These cell lines are capable of indefinite growth on a large scale and are suitable hosts for stable integration of heterologous DNA.

Stable expression results from integration into the host-cell genome of the gene for the expression of the heterologous protein. The integrated gene is transcribed efficiently and the protein is expressed persistently over many generations by the host cell. A stable producer-cell line typically provides ~1 to 10 mg of secreted protein per 10^9 cells per day (specific productivity). For monoclonal antibody production, productivity levels of 35 to 100 mg per 10^9 viable cells per day in myeloma cells (Bebbington et al., 1992; Shitara et al., 1994) and 15 to 110 mg per 10^9 viable cells per day in CHO cells (Page and Sydenham, 1991) are obtainable. Such levels may allow secreted-antibody titers of 1 to 1.5 mg/liter to be achieved in optimized large-scale systems; hence these systems have been popular in biotechnology. Where protein is accumulated intracellularly, it may reach little more than 0.1% to 0.5% of total cell protein. Thus, the focus has tended to be on secretion of protein where significant amounts of product are obtainable.

The obvious drawback associated with stable expression in mammalian cells is the time required to obtain stable productive cell banks (months) versus that required to obtain large amounts of non-post-translationally modified proteins in *E. coli* or large quantities of high-mannose-containing glycoprotein using yeast and insect cells (2 to 3 weeks). The advantages of obtaining the more complex proteins from mammalian cells include the ability to understand how these molecules interact in biological models both in vitro and in vivo. Using mammalian systems, much knowledge has been gained in the understanding of post-translational modification, protein quality control, and protein translocation. This knowledge ultimately facilitates improved expression in mammalian hosts.

Stable expression requires the transfer of the foreign DNA, along with the relevant DNA-based signals for transcription by RNA polymerase II, into the chromosomal DNA of the host cell (e.g., CHO). A suitable plasmid vector is required to carry the functions through to the host DNA. Vectors are commercially available from a variety of vendors—e.g., Invitrogen, Clontech, and Promega (see *SUPPLIERS APPENDIX*). A large variety of vectors are described in Pouwels et al. (1988). Suitable replicons contain 5 to 10 kb of DNA and usually are designed to contain phenotypic markers for selection in *E. coli* (e.g., Ap^r) and CHO cells ($DHFR^+$). Other features of appropriate plasmids include a promoter-distal cloning site along with other cloning sites; a replication origin for *E. coli*; a polyadenylation sequence from SV40 or bovine growth hormone; a eukaryotic origin of replication (e.g., SV40 or oriP); the gene for expression of the protein in a site proximal to the promoter; and a promoter and associated elements. Commonly used constitutive promoters for CHO cell applications are the SV40 early promoter (Moreau et al., 1981; Neuhaus et al., 1984), the adenovirus late promoter (McKnight and Tjian, 1986), and the cytomegalovirus (CMV) early promoter (Boshart et al., 1985). Transcriptional enhancers such as the human CMV enhancer (Boshart et al.,

RCU IAS/CGPM UNIVERSITY LIBRARY

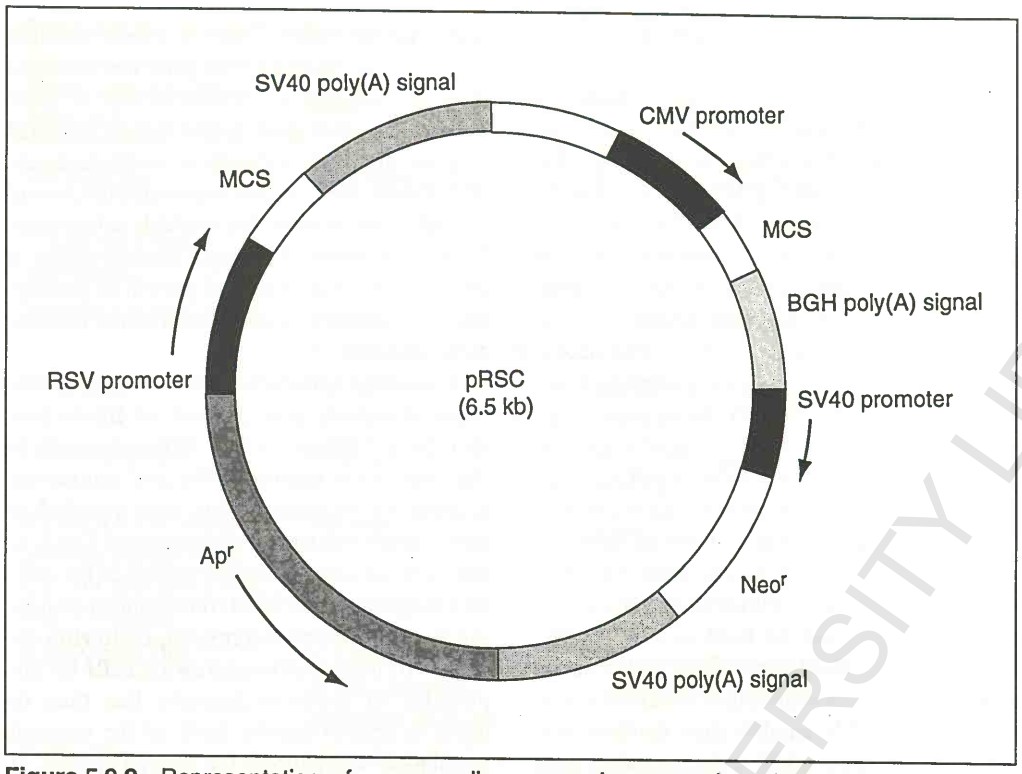

Figure 5.9.2 Representation of a mammalian expression vector based on the vector pRSC, published by Tsang et al. (1997); adapted with permission. The plasmid has two multiple cloning sites (MCSs) and three promoters. One promoter drives the neomycin-resistance protein while the remaining two MCSs have specific promoters and can be used to incorporate an amplification marker (DHFR) and a gene for the protein of interest.

1985) can enhance transcriptional activity by 10- to 100-fold and may be incorporated into the vector. These features are illustrated in Figure 5.9.2.

CHO cells have been used extensively as a host for stable expression of proteins. A number of CHO mutants have been developed that provide the user with tools to examine the synthesis of DNA, RNA, and protein as well as protein secretion, protein glycosylation, and intermediary metabolism. The most popular CHO sublines (also see Urlaub and Chasin, 1980) are CHO DXB11 (*dhfr*$^+$/*dhfr*$^-$) and CHO DG44 (*dhfr*$^-$/*dhfr*$^-$). The DXB11 cell was derived from CHO-K1 in 1978 by Lawrence Chasin. The CHO-K1 cells were originally derived in the 1950s, and the cells that were used in Chasin's laboratory for the development of the DXB11 line were obtained from Ted Puck and Fa-ten Kao at the Eleanor Roosevelt Cancer Institute in Denver in 1970. The DG44 cell line contains a double mutation in the *dhfr* genes and is not capable of natural reversion to the *dhfr*$^+$ phenotype. The DG44 cell line was derived from CHO pro3$^-$ cells by Chasin in 1982. The CHO pro3$^-$ was derived from the cell line established in the 1950s and is sometimes referred to as CHO Toronto, because it was used extensively in that city by Louis Siminivitch and colleagues. Both these cell lines can be obtained from Dr. Lawrence Chasin of Columbia University (e-mail: *lac2@columbia.edu*). Other mutants have been produced, and a brief list is included in Wirth and Hauser (1993).

TRANSFECTION, SELECTION, AND AMPLIFICATION

For introduction of genetic material into mammalian cells, three types of vectors are available—viruses, plasmid vectors with a replicon for animal cells, and plasmid vectors without a replicon for animal cells. Most viruses that replicate in mammalian cells ultimately cause death and lysis of the host cell, so expression of virus-borne genes is transient and can only be obtained over a short period prior to lysis. Retroviruses are capable of integrating genetic material into the chromosome of host cells—i.e., stable transformation. As with viruses, the use of plasmid vectors can result in either stable or transient expression of a gene product; the plasmid vectors without a mam-

BOSTON PUBLIC LIBRARY

malian cell replicon would require stable integration for expression of gene product.

Stable production of foreign proteins by mammalian cells requires use of a host cell line that is capable of incorporating the heterologous-gene DNA into a chromosome. In addition to the need for successful stable integration, a selection method is needed to fish out the stable transformants from the large population of cells that may contain unstable, intracellular heterologous gene copies. This necessitates cotransfection of a gene conferring some unique phenotypic property. Resistance to cytotoxic drugs is the most frequently applied method for selection of stable transformants. Normally, a gene for recessive drug resistance would be cotransfected into a host cell deficient in that particular activity. The most common approach is the use of dihydrofolate reductase (DHFR), which can be used as a selectable marker in DHFR-deficient CHO cells (Kaufman and Sharp, 1982). Other common transfectable selectable amplification markers that can be used with CHO cells are adenosine deaminase (in presence of inhibitors of ADA or cytotoxic levels of adenine or its analogs) in CHO DXB11 (DHFR$^-$; Yeung et al., 1983; Kaufman et al., 1986b); carbamyl phosphate synthetase–aspartate transcarbamylase–dihydroorotase in CHO UrdA mutant cells (de Saint Vincent et al., 1981); asparagine synthetase in CHO N3 (AS$^-$) cells (Cartier and Stanners, 1990); glutamine synthetase in any CHO cell (Bebbington and Hentschel, 1987); ornithine decarboxylase in CHO C55.7 (ODC$^-$; Chiang and McConlogue, 1988); multiple drug resistance in any CHO cell (Kane et al., 1989); and a mutant DHFR (Leu 22 changed to Arg 22) which can be used in any CHO cell host (Simonsen and Levinson, 1983). See Mortensen et al. (1997) for additional discussion of the use of selectable markers with mammalian cells.

It has been reported that a highly variable but typically large fraction (20% to 100%) of CHO clones established through calcium phosphate– or lipofection-mediated cotransfections (of *dhfr* and heterologous protein genes) coexpressed the dual-transfected expression vectors (Wurm and Petropoulos, 1994). It is likely that integration occurs at random sites. Given that the mammalian-cell genome is large (>10^9 bp), has 20% to 30% of the DNA as single-copy, and has only 0.1% of the genomic DNA containing coding sequences, it is critical to exert selective pressure to screen out the large number of nonproductive clones. Further amplification in the presence of selective pressure is necessary to obtain clones in which multiple copies of the heterologous gene are obtained through coamplification with the *dhfr* or other selectable marker gene. In this respect it is wise to screen for high producers at moderate levels of methotrexate (<1 μM) to prevent enrichment of high-copy-number but unstable integrands. Stability is assessed through determination of productivity after extended growth or passaging in the absence of selective pressure in complete medium.

Following transfection of cells using calcium phosphate precipitation or lipofection (Kaufman, 1990a), ~5% to 50% of the cells in the population acquire DNA and transiently express the encoded protein over a period of days before unstable, nonintegrated DNA is lost from the cells. A smaller portion of the cells will integrate the DNA chromosomally, resulting in stable protein expression. Following selection of these stable-expressing cells by application of selective pressure, less than or equal to approximately 0.1% of the original population will express the foreign protein. It is thus imperative to use selective pressure in the production of the early stable-expressing clones to prevent overgrowth with nonproducing cells. For CHO *dhfr*$^-$ host–based production, the cells are grown in medium deficient in nucleosides (e.g., α-MEM medium from Life Technologies), containing serum that has been dialyzed (to remove low-molecular-weight nucleosides such as hypoxanthine), and supplemented with 0.1 to 1.0 μM methotrexate. In deficient medium, the cell's requirement for purine and pyrimidine nucleosides is satisfied by the action of heterologous dihydrofolate reductase, which converts folate from the medium to tetrahydrofolate (FH_4). FH_4 and serine are then used by cellular serine hydroxymethyl transferase to provide methylene-FH_4 which can go on to donate C1 units in the reactions required for inosinic acid and thymidine production. Cells that acquire the capacity to express *DHFR* can be selected by medium deficient in nucleosides. Stepwise increases in the methotrexate concentration with increased passaging in deficient medium will select for cells containing high copy number of *DHFR* (Kaufman, 1990b).

PROTEIN TRANSLATION, QUALITY CONTROL, AND COVALENT MODIFICATION

Mammalian cells are complex factories with large numbers of compartments, each with specialized functions. Synthesis of proteins begins

Table 5.9.2 Protein Translocation and Post-Translational Modification Signals

Protein-based signal sequence	Related cell function	Example	Reference
$KDEL_{COOH}$	Retention in ER	BiP, protein disulfide isomerase, prolyl isomerase	Pelham and Bienz (1982)
Transmembrane sequences	Golgi retention	Coronavirus matrix protein	Mayer et al. (1988); Machamer and Rose (1987)
Mannose-6-phosphate	Added in Golgi for transport to lysosome	Lysosomal hydrolases	Reitman and Kornberg (1981)
SKL_{COOH}	Peroxisomes	Luciferase acyl coenzyme A oxidase	Keller et al. (1987); Miyazawa et al. (1989)
Leader peptide	Mitochondria	CoXIV (cytochrome *c* oxidase subunit IV)	Hurt et al. (1984)
RRNRRRRW (other specific signals exist, e.g., for p53 and SV40 late T antigen)	Nucleus	Rev	Malim et al. (1989)
Asn-X-Ser(Thr)	N-linked glycosylation in ER (dolichol precursor addition)	Many normal secreted and recombinant proteins	Hirschberg and Snider (1987)
O-Ser/Thr	Golgi-based O-glycosylation	Includes some recombinant proteins—e.g., IL-2, tPA	Hart et al. (1988); Conradt et al. (1990)
Cys (ER) Cys (Golgi)	Palmitoylation Myristoylation	Membrane anchoring—e.g., HBV preS1	McIlhinney (1990)
Tyr (Golgi)	Sulfation	Biological function	Rosenquist and Nicholas (1993); Han and Martinage (1992)
Tyr (cell-surface kinases)	Phosphorylation	Signal transduction and some viral proteins—e.g., HBV core	Myers et al. (1994); Albin and Robinson (1980); Aitken (1996)
Asn, Asp (Golgi)	Hydroxylation	Biological function	Stenflo et al. (1989)
Glu (Golgi)	γ-carboxyglutamate	Calcium binding—e.g., blood-cascade factors	Suttie (1985); Kaufman et al. (1986a)

in the nucleus with transcription and progresses to the cytoplasm, where translation and translocation into the endoplasmic reticulum (ER) occurs. The protein can contain sequences (motifs) that will order specific post-translational modifications as the protein progresses through the ER into the Golgi and before reaching the final destination either as a secreted protein or as a specialized resident cellular protein (see Table 5.9.2). In general, initiation of gene-transcription is the rate-limiting step. The rate of transcription elongation is constant until the movement of RNA polymerase II is stopped by termination signals. It follows that a highly expressed gene would be distinguished by the presence of a high density of polymerase molecules, resulting from high-frequency initiation.

For recombinant proteins that are destined for secretion, the translocation of expressed protein follows the so-called constitutive route (Walter and Lingappa, 1986), which is shown in part in Figure 5.9.3. A signal-recognition particle (SRP) binds to the signal sequence of the growing peptide when it protrudes into the cytoplasm, thereby halting further synthesis of the protein until the ribosome-SRP complex has bound to the docking protein (SRP receptor) at the ER membrane. Protein synthesis then continues and the peptide chain progresses into the lumen of the ER. At this point the amino-terminal signal sequence is cleaved off. Signal peptides encompass 13 to 30 amino acids. They usually have a net positive charge at the N terminus, a core of nine or more hydrophobic amino acids, and a cleavage site (Von Heijne, 1983, 1984). The tissue plasminogen activator

BOSTON CENTRAL UNIVERSITY LIBRARY

(tPA) leader peptide has been used for efficient translocation (Burke et al., 1986). The protein is folded and glycosylation is initiated in the ER. Detailed discussion of the intracellular factors involved in protein translocation are given in a number of excellent reviews (Gething and Sambrook, 1992; Rothman and Orci, 1992; Wirth and Hauser, 1993; Rothman, 1994).

The protein begins to fold cotranslationally in the ER. The ER provides an environment optimized for protein folding and is distinguished by a relatively high concentration of calcium (Baumann et al., 1991). The folding and stability of some proteins is calcium-dependent (Lodish and Kong, 1990). Another significant feature of the ER is that its redox potential is sufficiently high to enable disulfide-bond formation (Hwang et al., 1992). It appears

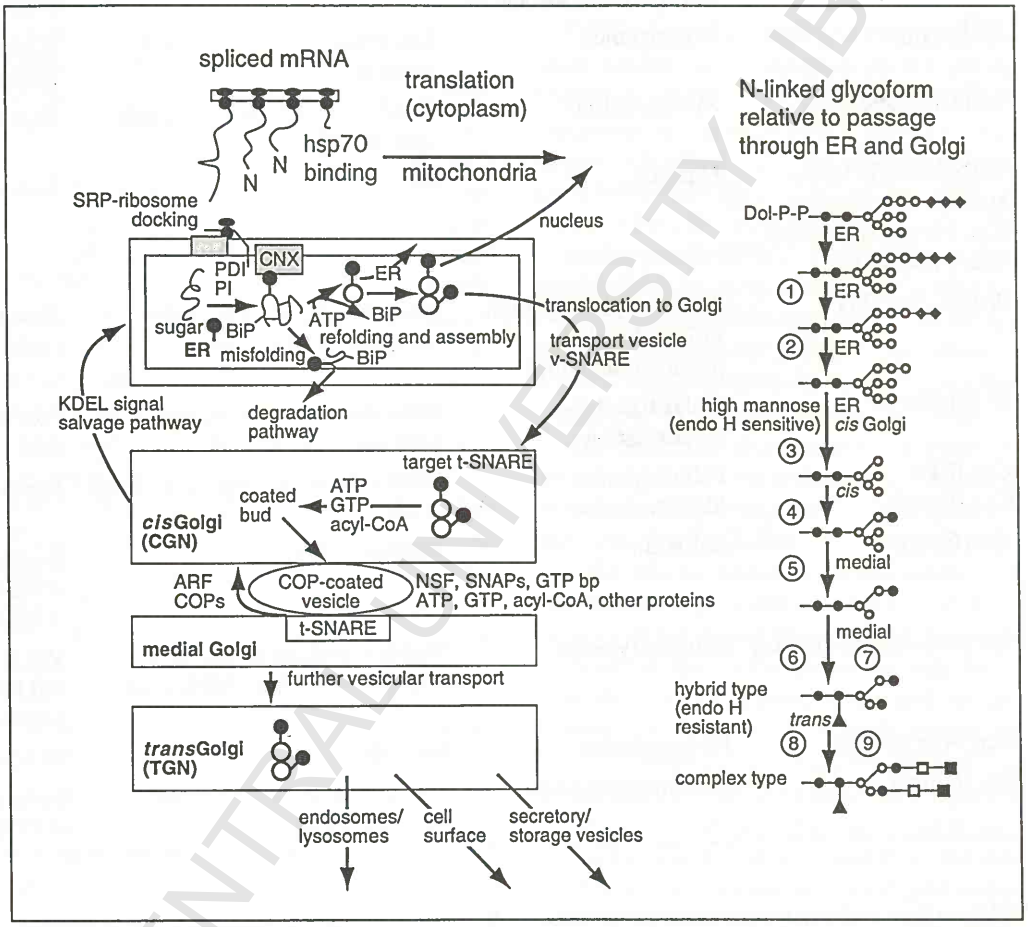

Figure 5.9.3 Intracellular protein translation and cisternal transport. Cytoplasmic translation results in a nascent polypeptide that is chaperoned by the hsp70 protein, which may direct the ribosome-peptide complex to the mitochondrion or the ER upon N-terminal peptide signaling. A signal-recognition particle (SRP) binds to the signal sequence, halting translation until it has docked at the SRP receptor. The hsp70 protein maintains the protein in a translocation-competent state, enabling membrane protrusion. Inside the ER the protein undergoes refolding assisted by protein disulfide isomerase (PDI), BiP, and calnexin (CXN). Initial N-glycosylation takes place cotranslationally in the ER. Misfolded protein, associated with BiP, is retained and eventually degraded. Transport of folded, assembled protein between the ER and Golgi cisternae occurs through a series consisting of budding, vesicle formation, and specific binding to target cisternae surfaces, through to the *trans* Golgi (TGN), where distribution to particular destinations occurs. **Abbreviations:** ARF, ADP-ribosylation factor; COPs, a family of coat proteins; Dol, dolichol; endo H, endoglycosidase H; GTP bp, GTP binding protein; NSF, NEM-sensitive cytosolic factor (identical to yeast sec 18p); SNAPs, three soluble NSF attachment proteins; v-SNARE and t-SNARE, SNAP receptors. **Symbols:** solid circles, N-acetyl glucosamine; open circles, mannose; solid diamonds, glucose; open squares, galactose; solid squares, sialic acid; solid triangles, fucose; circled 1, α-glucosidase I; circled 2, α-glucosidase II; circled 3, α-1,2-mannosidase; circled 4, GlcNAc transferase I; circled 5, α-mannosidase II; circled 6, GlcNAc transferase II; circled 7, α-1,6-fucosyl transferase; circled 8, β-1,4-galactose transferase; and circled 9, α-2,3-sialyl transferase.

BCU IAS CENTRAL UNIVERSITY LIBRARY

that glutathione is the redox buffer and that the redox potential of the ER is 20 to 100 times more oxidizing than that of the cytosol as indicated by the GSH/GSSG ratios (between 1:1 and 1:3 in the ER as compared to between 30:1 and 100:1 in the cytosol; Hwang et al., 1992). The ER contains soluble folding enzymes such as protein disulfide isomerase (PDI) and prolyl isomerase, which serve to aid the refolding process. Another group of proteins known as chaperones (Ellis and Hemmingsen, 1989) are present in the ER and appear to assist in protein folding and to ensure that incorrectly folded protein is not released from the ER, thus playing a quality-assurance role for newly synthesized protein in the cell. The best-studied chaperone is the glucose response protein BiP (or GRP 78), a member of the hsp70 family of proteins (Munro and Pelham, 1987; Hendershot et al., 1988). An ER integral membrane protein called calnexin (Bergeron et al., 1994) also appears to function in quality control of protein folding in the ER and affects the retention of incorrectly folded protein. Calnexin is unrelated to the heat-shock chaperone Hsp60, Hsp70, and Hsp90 families.

As the protein is folding in the ER, N-linked oligosaccharides are added to the nascent chain via dolichol phosphate. Intramolecular disulfide bonds are formed with the assistance of protein disulfide isomerase (PDI), and the molecular chaperone BiP/GRP78 associates with the refolding peptide chain. Multiple cycles of BiP binding and release occur in a process that requires ATP. Protein folding occurs with high efficiency and with a half-time on the order of 1 min. Pulse-chase studies of hepatitis B surface antigen (HBVsAg) secretion in mouse fibroblast cells (Huovila et al., 1992) showed that the formation of HBVsAg dimers in the ER occurred rapidly, within 2 min, while formation of higher-order oligomers occurred with a half-time of 2 hr. The study also provided evidence that the rate-limiting step was likely to be passage from the ER into the Golgi, as mature intracellular glycosylated HBV was not detected. The higher-order assembly of subunits or assembly of multimeric proteins begins in the ER and is likely completed in the so-called 15° compartment (named because of accumulation of molecules there at low temperature). This appeared to be the case for HBVsAg (Huovila et al., 1992). When a monomeric subunit is extensively folded, the BiP dissociates, and for multimeric proteins such as viral membrane proteins, subunit-subunit recognition and assembly occurs prior to transport into the Golgi complex (Doms et al., 1993). Only correctly folded protein progresses from the ER to the Golgi apparatus. Protein may be misfolded as a result of inefficient folding, mutations, heat shock, energy depletion, or addition of exogenous reductants such as dithiothreitol. These misfolded proteins usually form aggregates and typically display permanent and stable association with BiP. Aggregates are eventually degraded unless they are salvaged through a pathway that facilitates refolding from the misfolded protein species under specific conditions—e.g., altered temperature for temperature-sensitive folding mutants or where the ER environment is experimentally altered.

Proteins that have successfully folded in the ER are destined for secretion to the plasma membrane or the intracellular compartments, including the ER itself. Proteins destined to be retained in the ER possess the C-terminal signal sequence KDEL (Munro and Pelham, 1987). Proteins containing the KDEL signal that escape the ER are efficiently salvaged from the Golgi through a divalent cation–dependent receptor-based salvage pathway (Rothman and Orci, 1992). Proteins destined to be integrated into the ER membrane have a signal consisting of two lysine residues separated by three and four or five amino acids apart from the C terminus (Jackson et al., 1990). Signals for Golgi retention appear to involve histidine and cysteine within the membrane-spanning domain (Aoki et al., 1992).

N-linked oligosaccharide assembly begins in the ER compartment (Kornfeld and Kornfeld, 1985). In brief, N-linked glycosylation begins with synthesis of a lipid-linked oligosaccharide moiety—$Glc_3Man_9GlcNAc_2$-P-P-dolichol—which is transferred to the nascent peptide chain at the relevant Asn-X-Ser/Thr sequon site (i.e., peptide sequence recognition site). Truncations of the initial oligosaccharide structure follow this initial step in the ER. The folded and primary-glycosylated protein is transported to the Golgi, where maturation of the carbohydrate chains takes place. O-glycosylation is thought to occur after the N-glycosylation in the ER or the early part of the Golgi.

Differences in glycosylation of a given protein are a result of divergence in the Golgi-based processing of the oligosaccharides in different cell types (Jenkins et al., 1996). The human lymphoblastoid Namalwa cell line performs O- and N-linked glycosylation of recombinant tPA efficiently to produce human-type glycosylation characteristics (Okamoto et al., 1991; Khan et al., 1995). Most CHO cell lines

B. C. U. „M. I. ... 'AŞI

used in production of recombinant proteins do not possess active α1,3-galactosyltransferase, although the gene is present in these cells, which make low levels of galactosamine neuraminic acid. CHO and BHK cells also lack a functional α2,6-sialyltransferase enzyme and synthesize exclusively α2,3–linked terminal sialic acids via α2,3-sialyltransferase, in contrast to human cell lines, which contain both enzymes (Lee et al., 1989). In CHO cells the dominant sialic acid found is N-acetyl neuraminic acid.

Transport of the protein through the secretory and endocytic pathways is mediated by small vesicles that bud off from one compartment and fuse to the next compartment (Rothman and Orci, 1992). The *cis* Golgi stack (CGN) and *trans* Golgi stack (TGN) are defined areas of the entire Golgi network. The CGN and TGN constitute the entry and exit faces, respectively, and are involved in sorting and distribution of the protein. The CGN includes the KDEL salvage pathway for ER-based proteins. The TGN is where proteins with differing final destinations—e.g., lysosomes, secretory vesicles, and plasma membrane—diverge. The Golgi consists of stacks of cisternae where carbohydrate-chain trimming and elongation as well as other covalent modifications occur. The mechanism of flow through the Golgi cisternae appears to involve assembly of coated vesicles, which then transfer to the next compartment with concomitant loss of the coat. The loss of coat is linked to GTP-dependent hydrolysis, while subsequent fusion at the destination cisternae is ATP-dependent and also involves an N-ethylmaleimide (NEM)-sensitive enzyme, Sec18p. The specificity of vesicle targeting involves a docking mechanism based on binding of soluble NEM-sensitive attachment protein (SNAP) to a receptor designated as SNARE. Heterogeneity in the SNARE family allows for specialization and the ability to direct a given protein in the appropriate direction by selective fusion to progressive cisternae and ultimately the destination membrane.

Although it is usually desirable to obtain secretion of protein out of the cell prior to purification, in some cases the goal may be to express a protein receptor that would be transported to the cell-surface membrane. This was described for the production of the erythropoietin EPO receptor (EPO-R) in transfected hematopoietic cells (Hilton et al., 1995). The polypeptide was mutated to improve EPO-R refolding in the ER and increase cell-surface expression. The protein was obtained as a crude extract from the cell culture medium following the completion of the cell culture process. The glycoprotein may then be purified for further physicochemical analysis or testing in biological assays and animal studies.

Some proteins are not normally secreted by mammalian cells. This is the case for ER-resident proteins such as BiP, prolyl isomerase, and protein disulfide isomerase, which contain the C-terminal ER-retention peptide sequence KDEL. Also, a number of proteins including receptors and signal-transduction proteins are expressed and retained in the cell or on the cell surface. In cases where specific inhibitors of glycosylation enzymes are added to the culture medium, proteins that are normally secreted may be poorly secreted and thus accumulate in the ER or Golgi of the cell (Hickman and Kornfeld, 1978). Release of these intracellular or surface proteins requires disruption of the cell using a method capable of breaking the cell membrane (homogenization); in cases where membrane association is expected, nonionic detergents at 0.1% to 0.5% (v/v) are used in the lysis buffer.

Covalent modifications of amino acids by mammalian cells are numerous and to some extent may be a feature of a particular cell type. For example the γ carboxylation of factor VIII, which is essential for clotting-cascade activity, can be accomplished in the BHK and human 293 cell lines. This microsome-based, vitamin K–dependent modification was nonfunctional in CHO cells that had been transformed with complementing genes for carboxylation (Wirth and Hauser, 1993). Other processing events occur during passage of the protein from the ER to the Golgi. These involve removal of certain residues from the carbohydrate chains—e.g., glucose and mannose trimming. Other sugars are added to the carbohydrate chains as the protein passes through the medial and *trans* Golgi—e.g., addition of *N*-acetylglucosamine, galactose-*N*-acetate, fucose, galactose, and sialic acid. O-linked glycosylation is important for stabilization of some proteins—e.g., low-density-lipoprotein (LDL) receptor (Kingsley et al., 1986).

GROWTH OF MAMMALIAN CELLS FOR PROTEIN EXPRESSION

Mammalian cell culture media are complex in comparison to the simple defined media used for propagation of bacteria and yeast. This complexity stems from the need to satisfy the many functions required for normal growth and

RCU IAS LIBRARY UNIVERSITY LIBRARY

metabolism of mammalian cells (Bettger and McKeehan, 1986). Nutrients must satisfy the requirements for growth, maintenance of the cell, and expression of products. Additional specific growth factors such as insulin or insulin-like growth factor (IGF) are usually required. Minimal nutritional requirements were first defined in the 1950s (Eagle, 1955). These early studies showed that thirteen amino acids (Arg, Cys, Gln, His, Ile, Leu, Lys, Met, Phe, Thr, Trp, Tyr, and Val), eight vitamins (biotin, folic acid, niacinamide, pantothenic acid, pyridoxine, riboflavin, and thiamine), and various salts and minerals (Na, K, Ca, Mg, Cl, PO_4, Fe, Zn, Se, and possibly Cu, Mn, Mo, and V, which are usually present as trace contaminants) are required. The commonly used CHO derivatives DXB11 and DG44 have an absolute requirement for proline that results from a genetic deficiency in the conversion of glutamic acid to glutamic γ-semialdehyde. Inorganic ions may function as catalysts or exert physiological effects. Glucose (5 to 20 mM) and glutamine (0.5 to 5 mM) are commonly used to provide the energy source for the cells. These are consumed at a rate proportional to the viable-cell concentration. Cultured mammalian cells do not use the complete tricarboxcylic acid (TCA) cycle, and the glucose-consumption rate is lower than the glutamine consumption rate. Consumption of glucose yields lactate and consumption of glutamine yields ammonia as the metabolic byproduct. Other nutrients are consumed at a rate proportional to the rate of increase in cell density. Yield-based uptake rates for amino acids by CHO DG 44 cells range from 0.1 mM tryptophan/10^9 cells to 0.8 mM arginine/10^9 cells at a specific growth rate (the rate of growth divided by the cell density) of 0.25 to 0.30 $days^{-1}$ (D. Gray, unpub. observ.), reflecting the relative incorporation frequency of the individual amino acids into general protein. CHO cells, like most mammalian cells, produce alanine as a result of glutaminolysis. Accumulation of ammonia, as a result of glutamine degradation in the medium and consumption by cells, may become inhibitory to cell growth and ultimately limit the density of the culture (Butler and Spier, 1984).

In addition, physiological parameters such as pH, osmolality, and redox potential must be kept within acceptable limits. The use of serum is often advocated and has been regarded as a source of important components such as hormones, lipids, and growth factors. These serum-borne ingredients provide some consumable nutritional components as well as mitogens or growth factors that overall are not consumed by the cells (Klinman and McKearn, 1981).

A further level of complication in mammalian-cell medium design occurs through the need to maintain balanced relationships between nutrients while maintaining the osmolality of the medium within the physiological constraints (290 to 380 mOsmol/kg).

Recent medium development has focused on reducing the need for high levels of serum (Jayme, 1991). Fetal bovine serum (FBS) is the most frequently used version of serum and can be obtained from HyClone (see *SUPPLIERS APPENDIX*). FBS costs ~$500 to $600 per liter and is a factor contributing to the high cost of producing commercial clinical lots of protein. There may be batch-to-batch variation in serum which necessitates screening by small T-flask or shake-flask growth studies with the chosen mammalian cell line. Serum contains ~35 mg/ml of protein, of which ~60% is albumin. Thus if 10% serum were added to medium, the level of initial exogenous protein in the media would be 3 to 5 mg/ml.

Growth of cells in low serum (<0.5% v/v) has been accomplished through step-wise adaptation of cells to growth in medium with low or zero serum. The important functions of serum are replaced by the addition of the lipid precursors choline, inositol, and ethanolamine, the polyamine putrescine, and recombinant insulin (Nucellin-Zn from Eli Lilly) at 1 to 5 mg/liter (Jenkins, 1990) along with $FeCl_3$/citrate (Keenan and Clynes, 1996). A number of serum-free media have been developed and are now commercially available from, e.g., BioWhittaker. Another approach to implementing protein-free media has been the genetic modification of CHO cells through incorporation of the heterologous genes coding for transferrin and IGF-1 (Pak et al., 1996). As a result of cellular expression of the IGF-1 and transferrin, the cell is then able to grow, without addition of exogenous proteins, in a modified DMEM/F12 medium supplemented with sodium selenite.

A major concern in producing recombinant protein in protein-free medium is the potential for proteolysis and glycosidase activity. Such activity results in processing of the polypeptide chain and degradation of the carbohydrate moiety (Gramer and Goochee, 1993; Teige et al., 1994). Serum contains endogenous protease inhibitors—e.g., α_2-macroglubulin (Barrett, 1981)—and for this reason may be a valuable reagent in its own right in cell culture media

UCSF LIBRARY

when the produced protein is susceptible to proteolysis. Sialidases retain significant activity at pH 7.0 and are active in cell culture supernatants. Caution should be taken to minimize cell lysis during the culture process if the goal is to minimize desialylation of the expressed protein. This may be achieved by harvesting the supernatants during the exponential-growth phase prior to the beginning of the decreasing-viability phase, chilling it, and adding sialidase inhibitors such as 2,3-dehydro-2-deoxy-*N*-acetylneuramic acid to the supernatant (Gramer et al., 1995). In batch culture in serum-free medium, cell viability may decrease rapidly at the end of culture, thereby releasing intracellular proteases and glycosidases into the culture medium, which may in turn cause rapid proteolysis and carbohydrate degradation of the product.

Production of sialylated forms of glycoproteins is important in clinical applications to avoid rapid clearance by asialo- and asialogalactoprotein receptors in the liver. The genes for some of the key enzymes in the glycosylation pathway have been transfected into CHO cells (Lee et al., 1989) in attempts to tailor the glycoforms. A number of CHO-glycosylation mutants have been made available that exhibit a defect in one or more steps in the pathway (Stanley, 1989). Erythropoietin (EPO) expressed in the CHO mutant Lec 3.2.8.1. exhibited less heterogeneity than EPO produced in wild-type CHO cells (Stanley, 1991).

Studies with CHO-320 cells in glucose-limited chemostat culture (using RPMI-1640 medium) at a low dilution rate of 0.008 day^{-1} (i.e., volume of fresh medium added to the reactor per day divided by the reactor medium volume) showed a deviation of the specific growth rate from the dilution rate and an increase in specific cell-death rate (i.e., rate of cell death per liter per day divided by the number of viable cells per liter), suggesting that a minimum specific growth rate of 0.011 day^{-1} existed (Hayter et al., 1993). In the same study, the specific rate of γ interferon (γ-IFN) production increased with the specific growth rate (μ), indicating growth-related product production. The pattern of γ-IFN glycosylation was similar at all growth rates except the lowest, where an increase in nonglycosylated γ-IFN was observed. This was further addressed using batch culture (Leelavatcharamas et al., 1994), where it was concluded that the growth-associated production was a reflection of a cell cycle–related phenomenon whereby lower growth rate resulted in a prolongation of the cell-cycle time with an increase in the relative frequency of the G_1 cells in the culture population. It was suggested that the G_1 phase is the least productive phase in the cell cycle of CHO cells. Similarly S phase–specific synthesis of dihydrofolate reductase in nontransfected CHO-K1 cells was observed in which the maximum peak of DHFR activity coincided with the maximum rate of DNA synthesis in late S phase (Mariani et al., 1981). The expression of recombinant β-galactosidase by the CMV late promoter in CHO βG72-16 was shown to be S-phase related (Gu et al., 1993). It is likely that CHO cells will generally exhibit an S-phase dependency for expression of foreign genes using the typical promoter elements such as the CMV late promoter, and that a direct correlation of specific heterologous protein production rate with specific growth rate will be observed (Bock et al., 1993; Gu et al., 1996). As growth rate increases, the ratio of $S/(G_1 + G_2/M)$ increases (Hooker et al., 1995) and the frequency of cells in productive S phase in the culture increases.

A given glycoprotein produced in cell culture by mammalian cells will present a population of molecules exhibiting differences in glycosylation. The existence of families of structurally related yet distinct carbohydrate chains makes structural analysis of a distinct species complicated, since it is difficult to separate and purify the structural variants. Variation may result from incomplete occupancy of a directed site on the protein and from carbohydrate-structure variations imparted to the cells via cell culture–based conditions. Furthermore the action of glycosidases in the extracellular environment, particularly during batch culture, may degrade the carbohydrate structure of secreted glycoprotein, leading to a wider range of carbohydrate structures in the population. Changes in the oligosaccharides of the glycoprotein may lead to diminished biological efficacy in vivo—e.g., through increased clearance—or may enhance unwanted antigenicity of the molecule in a clinical application (Goochee et al., 1991).

Antibodies produced in CHO cells in serum-containing medium exhibited more galactosylation compared to antibodies produced by cells grown in serum-free medium (Lifely et al., 1995). The culture-medium glucose concentration affected the degree of glycosylation of γ-IFN produced in CHO cells in continuous culture (Hayter et al., 1992). Lipid supplements, with or without lipid carriers such as lipoprotein, appeared to increase N-glycosylation-site occupancy in γ-IFN (Jenkins et al.,

RCU IAS LIBRARY

Table 5.9.3 Estimated Quantity of Foreign Protein Produced by a Given Production System[a]

System	Vol. of medium in system	Total cells in system (vol. × conc.)	Total product in system[b]
Batch T-flask (T-175):			
175 cm^2 attached growth in DMEM/F12/10% serum[c]	75 ml	1.8×10^7	0.5-1 mg
Batch shake flask (250 ml), 0.5-1% serum[c]	100 ml	2×10^8	2-4 mg
Batch 5-liter spinner flask[c]	1000 ml	1×10^9	10-20 mg
Batch 5-liter spinner flask fitted with O_2 frit sparger[c]	1000 ml	2×10^9	20-40 mg
Batch 15-liter bioreactor with pH and O_2 control[c]	10 liters	2×10^{10}	200-400 mg
Continuous-mode 15-liter perfusion reactor with pH and O_2 control and cell retention	5-20 liter perfusion per day	1×10^{11}	100-400 mg per day

[a]Quantities assume a specific productivity of 1 to 4 mg/10^9 viable cells per day.

[b]Production of recombinant intracellular protein may achieve ~0.1% of total cell protein.

[c]Batch culture would be performed for 4 days after inoculation of 1×10^5 viable cells/ml.

1994). In perfusion culture of BHK-21 cells producing a recombinant interleukin 2 (IL-2) mutant, nutrient limitations (i.e., glucose, amino acids, and dissolved O_2) led to short-term changes in the general level of glycosylation, but the specific type of sugar incorporated was largely unchanged (Gawlitzek et al., 1995).

Direct intervention in cell physiological processes has an impact on glycosylation. A decreased protein-synthesis rate following addition of cyclohexamide improved the glycosylation-site occupancy of recombinant prolactin produced by C127 cells (Shelikoff et al., 1994). Low concentrations of dithiothreitol, which prevent cotranslational disulfide-bond formation in the ER, led to complete glycosylation of tPA at a tripeptide sequon that normally exhibited variable occupancy (Allen et al., 1995). This suggests that refolding may in itself limit the accessibility of glycosylation sites.

Sodium butyrate is sometimes used to improve protein synthesis, but it can change glycosylation by inducing the GlcNAc-transferase involved in O-glycosylation (Datti and Dennis, 1993) and by increasing sialyltransferase activity in recombinant CHO cells (Chotigeat et al., 1994; Gebert and Gray, 1995).

SCALE OF OPERATION

Batch growth in shake flasks or spinner flasks may provide titers in stable producer cell lines of 10 to 50 mg/liter, thus yielding up to 30 to 150 mg of crude secreted product which may then be purified from the culture supernatant. Following purification, the researcher may recover ~10% to 30% of the protein. Thus, small laboratory-scale cell culture may provide 3 to 50 mg of pure protein (>90% purity). Larger quantities of material require use of bioreactors in which pH, dissolved O_2, temperature, and stirring may be controlled. Should the user wish to control the cell growth rate during the production of the product, a continuous reactor may be used at a fixed dilution rate. In cases where high cell density is desired, the mode of operation would be continuous medium perfusion with cell retention in the bioreactor. Tables 5.9.3 and 5.9.4 provide some guidance for the likely scale requirements for a given objective.

The bioreactor environment may influence the product quality. Mild hypoxia may decrease the specific activity of sialyl transferase and hence the sialylation of the oligosaccharide chain, as was observed with recombinant human follicle-stimulating hormone produced in CHO cells at 10% dissolved oxygen saturation (Chotigeat et al., 1994). It appears that pH values within the range 6.9 to 8.2 have no dramatic effect on glycosylation, but clearly optimal growth would require control of pH within a narrower range, typically 7.0 to 7.4.

Metabolic byproducts may be the limiting factors in achieving high cell density in perfu-

BOSTON UNIVERSITY LIBRARY

Table 5.9.4 Typical Protein Requirements for Various Analyses

Assay	Quantity of protein required	Comments
ELISA	<5 µg	Identification of activity possible with crude extract
Amino acid analysis and sequencing (including development of method)	20 µg	Pure protein required; thus starting requirement would be >100 µg in order to account for purification losses
Carbohydrate analysis	20 µg	Pure protein required
Extinction-coefficient determination	500 µg	Pure protein required; thus starting requirement would be 3-5 mg
Biological testing in animal-based model	50 mg	Must obtain suitable purity of product to prevent collateral effects on physiology due to contaminants
Human clinical trials	1-100 g	>95% purity; requires extensive testing to ensure safety

sion culture. Increases in ammonium ion concentration to 10 mM in the culture medium resulted in substantial growth inhibition in hybridoma cells (McQueen and Bailey, 1990) and appeared to inhibit growth in most cell lines. The likely cause of this is the transport of ammonium ion by membrane-bound ion pumps and ultimate acidification of the cytoplasm (Martinelle et al., 1996). Lower levels of ammonia (~2 mM) may exert influences on glycosylation (Andersen et al., 1994). One approach to eliminating this potential inhibition of cell growth is through adaptation to a nonammoniagenic medium. This medium would contain glutamate or 2-oxoglutarate in place of glutamine (Hassel and Butler, 1990). Lactate generated from glucose can also reach growth inhibitory levels at >15 mM. Optimization of medium and perfusion rate may enable reduction in the levels of lactate and ammonia, allowing higher cell density. Lowering the glucose level may reduce the yield of lactate, but concomitant limitation of glycosylation may occur. CO_2 may accumulate in high-density cultures, thereby exerting an inhibitory effect on the culture (Gray et al., 1996). Limitations that are due to CO_2 accumulation may be overcome by choosing an optimal sparging strategy.

Finally mammalian cells are weaker and larger than bacterial cells and limits to the degree of agitation are important to prevent cell damage and death. Where agitation is used in reactors or in sample handling, cell damage at the gas-liquid interface as well as bubble damage can be reduced by adding low levels—<0.1% (w/v)—of the surfactant pluronic polyol (Murhammer and Goochee, 1990).

SUMMARY

Both yeast and *E. coli* heterologous protein expression are very well defined. The components of these expression systems are easily obtained through many commercial vendors. Use of these systems enables the researcher to obtain large amounts of pure material in a short period of time. In contrast, mammalian expression systems are not comprehensively defined or understood and require a significant investment of time before heterologous protein is obtained. At the present time the mammalian expression systems are not available as turnkey, catalog-based systems. The user must define the components for a particular application. Although this complexity exists with the mammalian cell–based systems, they are uniquely important for the production of glycoproteins that possess oligosaccharides close to or identical to those of human origin. Proteins secreted by mammalian cells possess correct conformations and exhibit full biological activity. The ability to transfer foreign DNA into these cells enables a greater understanding of the mammalian cell transcriptional, translational, and post-translational machinery. The ability to incorporate foreign gene sequences into a mammalian-cell chromosome and the ability to grow mammalian cells in suspension in large-scale bioreactors has enabled the production of large quantities of pure clinically important proteins.

Production of Recombinant Proteins in Mammalian Cells

Mammalian cells are the relevant hosts for expression of properly folded glycoproteins that possess post-translational modifications and that have biological activities similar to those of proteins derived from human cells (*UNIT 5.9*). Increasing interest in the production of glycoproteins (Chapter 12) for clinical application and as reagents for the study of biological mechanisms has led to greater use of mammalian cell protein expression systems. In response to this, developments in molecular biology and process science have provided mammalian cell expression vectors, cell lines, and growth media—and have established methods for high-density suspension culture in compact bioreactors.

When DNA is transferred into a mammalian host cell, the genes may be expressed without being integrated into the chromosomal DNA (transient expression). A small percentage of cells incorporate the DNA into a transcriptionally active chromosomal locus and may express the gene on a permanent basis from generation to generation (stable expression). In *UNIT 5.9* it was stated that the strategy for expression is dependent on the ultimate goal of the project. When one-time production of a few hundred micrograms of purified protein is sufficient, then rapid, transient ("burst production") expression of the gene in COS-7 cells (Aruffo, 1997), the vaccinia system (Earl and Moss, 1998; Earl et al., 1998a,b; Elroy-Stein and Moss, 1998; Moss and Earl, 1998), Sindbis virus (Invitrogen), or Semliki Forest virus (Liljestrom and Garoff, 1995) are appropriate. The best strategy for consistent production of larger quantities of pure protein is stable expression. Popular hosts for stable expression are Chinese hamster ovary (CHO) cells, baby hamster kidney (BHK-21) cells, myeloma cells, and the transformed kidney cell line 293. Protocols for stable production in CHO cells are described in this unit. Typical methods for transfection using commercially available plasmid expression vectors (see Table 5.10.1) are described, along with methods to select for stable expression and methods for amplifying the expression level in the transfected cell. Following this, procedures are presented for efficient cell growth to obtain significant amounts of protein product. A general flow scheme of the overall process is provided in Figure 5.9.1.

Stable expression is obtained when the gene of interest and associated expression elements (*cis* elements) are incorporated into a transcriptionally active region of the host cell chromosome. Production of the plasmid vector for use in transfection is usually performed in *E. coli* cells and the plasmid is purified using standard column chromatography methods (see Basic Protocol 1). DNA is transferred into the cell by lipofection (see Basic Protocol 2) or electroporation (see Alternate Protocol 1). Derivation of stable transfectants requires selection of clones producing the recombinant protein (see Basic Protocol 3, Support Protocol 1, and Alternate Protocol 2) and single-cell cloning (see Support Protocol 2), and as such is a more laborious process than the repeated transient-expression approach. Significant effort and time is needed for several rounds of gene amplification and selection because cell cloning and selection is required at each round. Although the additional work is a possible deterrent to use of this approach, it is possible to produce larger quantities of protein in this way. The other simple advantage of stable transfection is that cell banks can be produced, which enable reproducible production of the product. These advantages will more than provide a dividend after the initial investment of time. To obtain high-level expression, the gene amplification and selection processes can be combined (see Basic Protocol 4).

Growth of the production cells in spinner flasks and/or bioreactors is necessary to obtain sufficient total protein for further purification and study. Procedures for adapting cells to

[a]Abbreviations: hCMV, human cytomegalovirus (CMV) major immediate early promoter; *Hyg*, hygromycin phosphotransferase B gene; MSX, methionine sulfoximine gene; *Neo*, aminoglycoside phosphotransferase II gene; *Pac*, puromycin resistance gene; RSV, Rous sarcoma virus long terminal repeat; *Zeo*, Zeocin resistance gene.

suspension conditions and low-serum media are included (see Basic Protocol 5) as well as procedures for growing cells in various vessels and in batch culture (see Basic Protocols 6 and 7), and in continuous and perfusion cultures (see Alternate Protocol 3). Most often, the product is secreted into the medium and must be separated from the cells prior to subsequent storage or purification (see Basic Protocol 8). In some cases, the protein of interest may be intracellular or membrane-associated, and thus the cells become the product and must be harvested from the culture (see Basic Protocol 9).

Support protocols describe freezing of cells (see Support Protocol 3), determination of growth rates (see Support Protocols 4 and 5), determination of specific productivity of cells (see Support Protocols 6 and 7), preparing samples for assay (see Support Protocol 8), and setting up a 10-day shaker-flask growth curve (see Support Protocol 9).

NOTE: Milli-Q purified water or equivalent is used for all aqueous buffer reagents.

NOTE: All reagents and equipment coming into contact with live cells must be sterile, and proper sterile technique should be used accordingly.

NOTE: All culture incubations are performed in a humidified 37°C, 5% CO_2 incubator unless otherwise noted.

PCU IASRI CENTRAL UNIVERSITY LIBRARY

PLASMID PURIFICATION BY ALKALINE-LYSIS/ANION-EXCHANGE CAPTURE

The gene of interest (in the form of cDNA) is inserted into the multiple cloning region of the plasmid (which has been constructed with a number of restriction sites) after any required modifications in the sequence. Commercially available plasmids provide various choices of elements; a subset are shown in Figure 5.10.1.

Sufficient purified plasmid is produced in competent *E. coli* cells (e.g., strain DH5α) using the preparation approach discussed here. The alkaline-lysis/anion-exchange capture method is commonly used to prepare large amounts of DNA for transfection of host cells. A number of commercially available kits are available, as mentioned below, making this method quick and easy to use. Following DNA preparation, transfection of the CHO cells is performed using lipofection (see Basic Protocol 2) or electroporation (see Alternate Protocol 1).

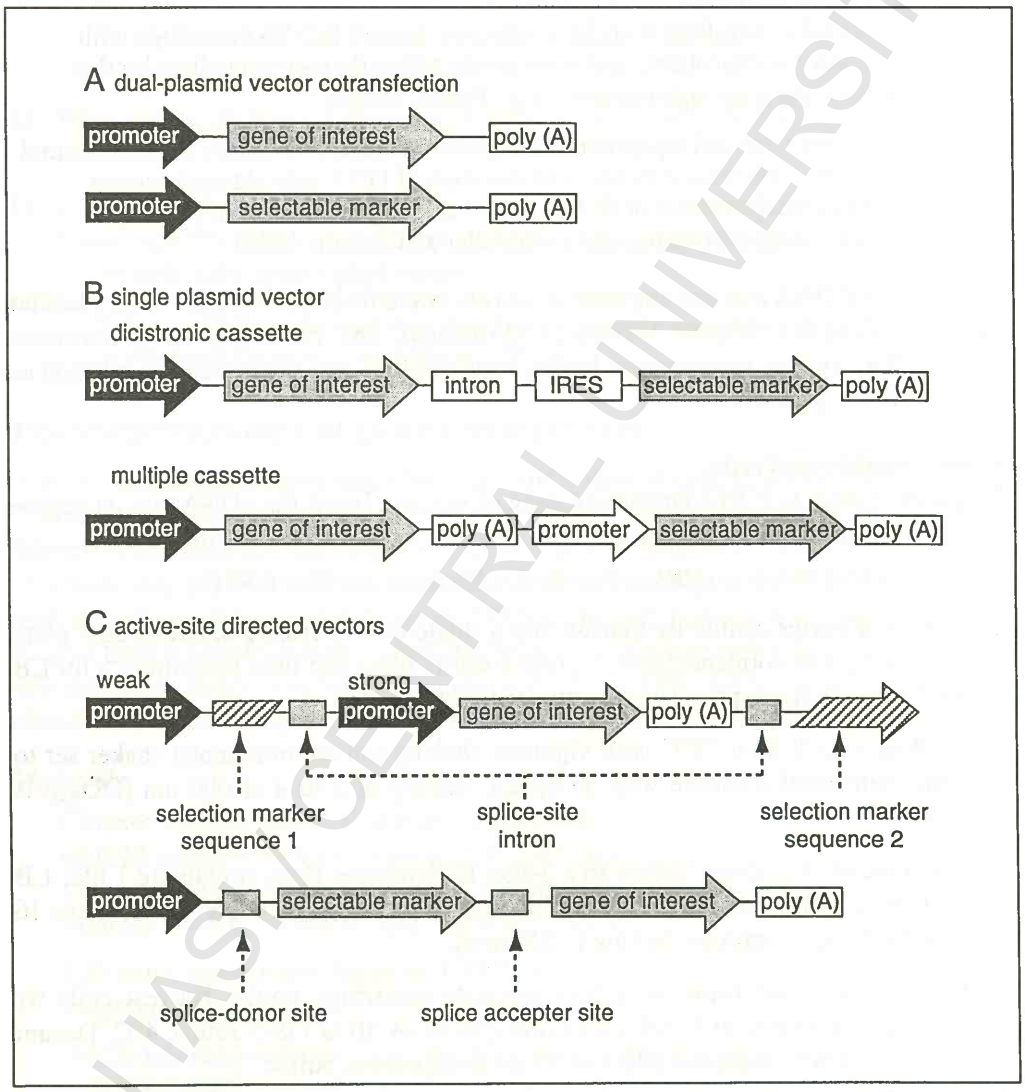

Figure 5.10.1 Expression vector elements for common transfection strategies. (**A**) Dual- and (**B**) single-plasmid vectors are shown for commercial vectors types described in Table 5.10.1. The active site–directed vectors (**C**) are reported throughout the literature (Lucas, 1996; Wurm et al., 1996); although not currently available as commercial catalog items, they may provide advantages in obtaining high expression levels. Abbreviations: IRES, internal ribosomal entry site.

BIAS / CENTRAL UNIVERSITY LIBRARY

Materials

cDNA containing gene of interest
Plasmid with appropriate *cis*-acting elements (Fig. 5.10.1 and *UNIT 5.2*)
Competent *E. coli* cells (e.g., strain DH5-α; Life Technologies)
LB medium (*UNIT 5.2*) containing antibiotics for selection (e.g, 100 µg/ml ampicillin, 40 µg/ml kanamycin, or 25 µg/ml tetracycline, depending on plasmid kit; all antibiotics available from Sigma)
Resuspension buffer (see recipe)
Lysis solution: 0.2 M NaOH/1% (w/v) SDS
Neutralization solution: 1.3 to 3.0 M potassium acetate, pH 4.8 to 5.5
Isopropanol
TE buffer (*APPENDIX 2E*)
80% ethanol

Sterile glass test tubes for bacterial culture
Environmental shaker (New Brunswick Scientific)
3-liter Erlenmeyer flask
Beckman J2-21 centrifuge with JA-10 rotor or Sorvall RC-5B centrifuge with GS-3 rotor (or equivalent) and appropriate polycarbonate centrifuge bottles
UV/visible light spectrophotometer (e.g., Perkin-Elmer)

Additional reagents and equipment for ligation of linkers to cDNA (Klickstein and Neve, 1991), plasmid selection and insertion of DNA into plasmid vectors (*UNIT 5.2*), transformation of *E. coli* (*UNIT 5.2*), and purification of DNA by anion-exchange chromatography (Budelier and Schorr, 1998)

NOTE: Several DNA plasmid preparation kits are available commercially—e.g., Plasmid Maxi Kit (Qiagen), Wizard Maxipreps (Promega), and FlexiPrep Kit (Pharmacia Biotech). Kits include resuspension buffer, lysis solution, and neutralization solution as described in the protocol.

Prepare transformed cells

1. Ligate linkers to cDNA containing gene of interest. Insert the cDNA into an appropriate plasmid vector and transform *E. coli* host cells with the vector (*UNIT 5.2*).

   Ligation of linkers to cDNA is described in Klickstein and Neve (1991).

2. Prepare a starter culture by transferring a single colony from a selective agar plate containing transformants (*UNIT 5.2*) into a sterile glass test tube containing 5 ml LB medium with the appropriate selective antibiotic.

3. Incubate 6 to 8 hr at 37°C with vigorous shaking (on environmental shaker set to ~300 rpm) until a culture with an optical density of 2 to 4 at 600 nm (OD_{600}) is obtained.

4. Add 1 ml of this starter culture to a 3-liter Ehrlenmeyer flask containing 1 liter LB medium with the same selective antibiotic used in step 2. Incubate culture 12 to 16 hr at 37°C with vigorous shaking (~300 rpm).

5. Transfer cell suspension to a polycarbonate centrifuge bottle. Harvest cells by centrifuging 15 min at 6,000 × *g* (6,000 rpm in JA-10 or GS-3 rotor), 4°C. Decant supernatant and resuspend pellet in 30 ml resuspension buffer.

Isolate plasmid DNA

6. Add 30 ml of lysis solution to resuspended cells. Mix thoroughly by inverting (not vortexing) and incubate ~10 min at room temperature.

   Cell lysis is complete when solution becomes relatively clear and viscous.

ECU IAS / CENTRAL UNIVERSITY LIBRARY

7. Add 30 ml of neutralization solution to the lysed cells and mix immediately by inverting.

8. Centrifuge 20 min at 10,000 to14,000 × *g*, (7,500 to 9,000 rpm in JA-10 or GS-3 rotor), 4° to 8°C.

   This step separates the cell debris from the lysate. The plasmid will be in the lysate.

9. Precipitate crude DNA from the clear lysate by adding 0.5 vol isopropanol, then centrifuge 30 min at 15,000 × *g* (9,200 rpm in JA-10 or GS-3 rotor), 4° to 8°C.

   Mark the region in the centrifuge tube where the pellet is expected to stick, as it may not be visible after isopropanol precipitation.

10. Dissolve DNA pellet in 2 ml TE buffer.

Purify plasmid DNA

11. Apply resuspended DNA solution to an anion-exchange resin (e.g., as provided with Qiagen Plasmid Maxi Kit; also see Budelier and Schorr, 1998).

    The plasmid DNA will bind to the resin. Budelier and Schorr (1998) describes the anion-exchange procedure for DNA.

12. Wash resin with 80% ethanol or with the wash buffer provided with the kit (Budelier and Schorr, 1998).

13. Elute DNA from resin with TE buffer or the elution buffer provided with the kit. Determine DNA concentration by measuring OD_{260} (50 µg/ml = 1.0 OD_{260}) using a UV/visible light spectrophotometer.

    The eluted DNA can be used directly in transfection of host cells (see Basic Protocol 2 and see Alternate Protocol 1) or stored at –20°C.

TRANSFECTION OF CELLS BY LIPOFECTION

BASIC PROTOCOL 2

A good method for transfecting CHO cells and adherent cells in general is lipofection. This technique can typically achieve a 50% transfection efficiency (Subramanian and Srienc, 1996), although the value depends on the sensitivity of detection. In the process of lipofection, plasmid DNA is complexed with cationic lipids; the lipid then interacts with the cell membrane and delivers the DNA to the cell. In the protocol below, the lipid reagent used is Lipofectamine, which has been very effective with CHO cells. There are several other lipids available commercially from Life Technologies, Boehringer Mannheim, and Invitrogen, which may be more suitable for other cell types.

Materials

Chinese hamster ovary (CHO) cells (Table 5.9.1)
αMEM medium with and without 10% FBS (see recipe)
Lipofectamine (Life Technologies; store up to 6 months at 4°C)
Plasmid DNA to be transfected (see Basic Protocol 1)

100-mm tissue culture dishes or T-75 flasks
Polystyrene tubes

Additional reagents and equipment for growing mammalian cells in culture (*APPENDIX 3C*)

1. Plate CHO cells, at a density of 1.5–3.0 × 10^6 viable cells per 100-mm tissue culture dish or T-75 flask, using αMEM medium/10% FBS. Incubate ~24 hr to achieve 50% 80% confluency (*APPENDIX 3C*).

BOWIE STATE UNIVERSITY LIBRARY

2. Dilute 48 µl of Lipofectamine in 0.8 ml serum-free αMEM in a polystyrene tube. Dilute 8 µg of DNA to be transfected in 0.8 ml serum-free αMEM in a separate polystyrene tube.
3. Mix lipid and DNA solutions and incubate 45 min at room temperature to form complexes. Dilute the complexes in 6.4 ml serum-free αMEM.
4. Wash cells with 10 to 20 ml serum-free αMEM per dish, remove the medium, then add the diluted lipid-DNA complexes to cells.

   Alternatively, the lipid-DNA complexes can be directly diluted in the tissue culture dish.
5. Incubate cells with the complexes for 5 to 6 hr under normal culture conditions. Replace complexes with αMEM/10% FBS, then incubate 24 to 48 hr.

   Note that the recipe for αMEM (see Reagents and Solutions) includes no antibiotics.

   Cells are ready for either transient analysis or selection (see Basic Protocol 3) 24 to 48 hr post-transfection.

ALTERNATE PROTOCOL 1

TRANSFECTION OF CELLS BY ELECTROPORATION

Electroporation allows delivery of DNA into cells by creation of transient pores in the cell membrane. In many cell types that grow in suspension, the lipofection method (see Basic Protocol 2) does not result in high transfection efficiencies. In these situations electroporation is an appropriate choice, as it has been shown to work with numerous cell types (both suspension and adherent). Electroporation may also be the preferred method when single-copy integration is desired, since this technique delivers lower amounts of DNA to the cell than lipofection. Both methods work well in the case of CHO cells. The authors have found that the Bio-Rad Gene Pulser II, equipped with a capacitance extender, is suitable for electroporation of mammalian cells. This instrument delivers a decaying exponential pulse. Other instruments—e.g., from BTX and Invitrogen—can also be used.

Additional Materials (also see Basic Protocol 2)

Electroporator and electroporation cuvettes with 0.4-cm electrode gap (Bio-Rad)

Additional reagents and equipment for growing mammalian cells in culture, trypsinizing cells, and counting viable cells by trypan blue exclusion (*APPENDIX 3C*)

1. Harvest exponentially growing (subconfluent) cultures by trypsinization and count cells (*APPENDIX 3C*). Centrifuge cells 10 min at 200 to 500 × *g*, room temperature. Resuspend pellet in αMEM/10% FBS medium at 1–2 × 10^7 viable cells/ml. Dispense 0.5-ml aliquots into electroporation cuvettes.
2. Add 10 to 20 µg of DNA to be transfected and incubate 10 min on ice.
3. Resuspend cells by flicking, then pulse at high capacitance (~1000 µF) at 200 to 400 V (which should result in a time delay in 5 to 20 msec range). Use 10- to 50-V steps.
4. Incubate electroporated cells 10 min at 37°C. Transfer cells into a T-75 flask or 100-mm dish with 20 ml of medium and incubate 24 to 48 hr under normal culture conditions (*APPENDIX 3C*).

   The cuvette may need to be rinsed for complete removal of cells.

   Cells are ready for either transient analysis or selection (see Basic Protocol 3) 24 to 48 hr post-transfection.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

SELECTION FOR NEOMYCIN PHOSPHOTRANSFERASE (NPTII) WITH GENETICIN (G418)

Following the transfection, cells are subjected to the selection process, in which they are exposed to a drug that allows cells expressing the resistance marker to survive while killing the rest. The commonly used dominant selection markers include neomycin phosphotransferase (NPTII, aminoglycoside phosphotransferase II) which enables growth in the presence of G418 (geneticin). Other selection approaches in common use are the glutamine synthetase (GS) system, which uses growth in glutamine-free medium for selection (Kingston et al., 1993). Another alternative and common approach is the use of a recessive marker such as dihydrofolate reductase (DHFR) with initial selection in nucleoside-free medium (see Basic Protocol 4).

Selection, as described in this protocol, and screening (see Alternate Protocol 2), are the two different methods that help isolate cells that express the marker gene. The marker gene is an indirect indication that the protein of interest is also being expressed. In selection, the drug kills cells that do not express the marker. This protocol describes selection with the commonly used dominant selection marker neomycin phosphotransferase II.

Materials

Culture of transformed cells at 50% to 70% confluency, in T-25 or T-75 flasks (24 to 48 hr post-transfection; see Basic Protocol 2 or Alternate Protocol 1)

Selective medium: αMEM medium (see recipe) containing 5% to 10% FBS and 0.1 to 1.0 mg/ml G418 (Geneticin, Life Technologies; add from 50 mg/ml stock prepared in 100 mM HEPES, pH 7.0 to 7.2; see Support Protocol 1 for optimization of concentration)

96-well flat-bottom tissue culture plates

Inverted microscope

T-75 tissue culture flasks

Additional reagents and equipment for growing mammalian cells in culture, trypsinizing cells, and counting viable cells by trypan blue exclusion (*APPENDIX 3C*)

1. At 24 to 48 hr post-transfection, harvest cells by trypsinization and count viable cells by trypan blue exclusion (*APPENDIX 3C*).
2. Plate 100 to 1000 cells in each well of a 96-well tissue culture plate using 200 µl selective medium per well. Begin incubation.
3. Replace selective medium once every 3 to 4 days and observe cells using an inverted microscope to monitor cell death and detachment.

   Large colonies of live cells (containing 100 to 200 cells) should appear within 3 weeks.
4. As the colonies grow and become confluent (indicated by change in color of the phenol red indicator in the medium from dark red to orange as the pH decreases), screen individual clones for the protein of interest using different methods depending on the targeting of the gene product.

   The supernatant is assayed for secreted proteins using an ELISA. For cytoplasmic proteins, the cells are screened through the detection of surrogate markers such as green fluorescent protein (GFP; Kahana and Silver, 1996). Membrane proteins may be amenable to immunofluorescent staining followed by flow cytometric sorting. An alternative approach is to pick 10 to 20 clones and screen cell lysates with ELISAs or immunoblots (UNIT 10.8). If the protein is localized to the membrane protein, immunofluorescent staining with specific antibodies (UNIT 10.10) can be directly applied.

BCU IAS/CENTRAL UNIVERSITY LIBRARY

5. Trypsinize viable productive colonies and transfer to wells of a 24-well plate, each containing 2 ml selective medium. After cells reach confluency, trypsinize and transfer to a T-75 flask with 20-ml medium (*APPENDIX 3C*).

When the attachment culture in a tissue culture flask grows to 80% to 90% confluency, it should be trypsinized and subcultured into a new flask with a starting cell density of 1 × 10^4/cm^2 for continuation of cell growth.

SUPPORT PROTOCOL 1

DETERMINATION OF BACKGROUND SENSITIVITY TO G418

The drug concentration and the plating cell density are very important for selection to be effective. In the case of selection, the optimal drug concentration is determined as described below. This concentration is set to the minimum required to kill nontransfected cells in 2 to 3 weeks. The selection becomes less stringent when cells are confluent, especially with G418 selection, probably because of lowered metabolic activity. It is important to choose a concentration of the toxic drug that will kill cells that are not expressing the resistance gene but that will allow growth.

Additional Materials (also see Basic Protocol 3)

Selective media containing various concentrations (100 to 1000 μg/ml in 100-μg/ml increments) of G418 (add from 50 mg/ml stock prepared in 100 mM HEPES, pH 7.0 to 7.2)
100-mm tissue culture dishes

1. Plate cells at a density of 0.6–1.2 × 10^6 per 100-mm dish in selective media containing G418 at various concentrations. Begin incubation.
2. Replace medium every 3 to 4 days and observe cells under inverted microscope.
3. Determine the minimum concentration of G418 required for complete killing of cells after 2 weeks.

ALTERNATE PROTOCOL 2

SCREENING OF GREEN FLUORESCENT PROTEIN BY FLOW CYTOMETRY

An alternative to selection (see Basic Protocol 3) is the process of screening, where cells expressing the protein of interest are detected in the population using a noninvasive method and then isolated using flow cytometry or other techniques such as affinity chromatography and magnetic-affinity cell sorting. These methods have not been developed extensively because few noninvasive detection methods have become available. In the protocol below, the green fluorescent protein (GFP; Kahana and Silver, 1996) has been used as a screening marker and provides a flow cytometric method for measuring single-cell fluorescence, which may be combined with sorting based on the signal (Subramanian and Srienc, 1996). Any membrane protein against which specific antibodies can be directed may be used instead of GFP. An additional staining step is required when membrane proteins are used.

Materials

Cells transformed with plasmid (see Basic Protocol 2 or Alternate Protocol 1) containing GFP reporter gene (pIRES1-EGFP from Clontech or pTracer-CMV from Invitrogen) at 50% to 70% confluency in T-25 or T-75 flasks
1% (w/v) bovine serum albumin (BSA; Sigma) in PBS (*APPENDIX 2E*)
10× (0.05 mg/ml) propidium iodide stock (PI; Molecular Probes; optional)
Appropriate culture medium

PCU IASTRAL UNIVERSITY LIBRARY

Flow cytometer with cell sorting capability (FACS Vantage and FACSort from Becton Dickinson Immunocytometry Systems or EPICS Elite ESP cell sorter from Coulter Electronics or equivalent)
T-25 tissue culture flasks

Additional reagents and equipment for trypsinizing cells, counting viable cells by trypan blue exclusion, and growing mammalian cells in culture (*APPENDIX 3C*) and flow cytometry (Robinson et al., 1998)

1. At 24 to 48 hr post-transfection, harvest cells by trypsinization and count viable cells by trypan blue exclusion (*APPENDIX 3C*).

   Make sure cells are in single-cell suspension and not in clumps.

2. Resuspend cells at a concentration of ~1×10^6 cells/ml in 1% BSA/PBS. If desired, immediately before analysis, counterstain by adding 0.05 mg/ml (10×) PI to a final concentration of 5 µg/ml.

3. Run cells through flow cytometer at a flow rate of 200 to 1000 cells/sec. Tune laser wavelength to 488 nm and collect the following parameters:

   Forward-angle light scatter (FALS; linear)
   Right-angle light scatter (RALS; linear)
   Green fluorescence: linear and logarithmic using 510- to 540-nm band-pass (FITC) filter
   Red fluorescence (if counterstained with PI): linear or logarithmic using 670 or 690 long-pass filter.

   Gate on viable cells from bivariate plot of FALS versus RALS or FALS versus PI. Set gate to distinguish nonfluorescent from fluorescent cells, then select top 1% to 10% (or all) of the fluorescent cells for sorting (see Robinson et al., 1998, for detailed protocols in flow cytometry and cell sorting).

4. Sort 1×10^3 to 1×10^5 viable cells within the defined fluorescence threshold into a tube containing culture medium. Inoculate cells into T-25 flask with 5 to 10 ml culture medium. Begin incubation.

5. Sort cells again after 2 to 3 weeks, directly into 96-well plates containing 200 µl medium per well, at 1 cell/well. Continue incubation.

   Allow enough time for cells to establish a stable phenotype. Stringent criteria on GFP may be used at this step—i.e., selecting the top 1% or less of fluorescent cells (0.01% to 0.1% of cells can be sorted).

   After the clones grow out they can be screened for the production of the protein of interest.

SINGLE-CELL CLONING

SUPPORT PROTOCOL 2

After cells expressing the gene product have been selected, single-cell cloning is usually applied to obtained monoclonal cultures. This is usually done by diluting a cell suspension and plating the cells in 96-well plates so that only single cells result in colonies, which may then be isolated. The cell suspension should consist mainly of single cells, with no clumps, and the viable cell count should be accurate. Cell clumps after trypsinization should be carefully broken up by repeated pipetting. Since hemacytometer-based counts have a 20% standard deviation (even with two hemacytometers) it is recommended that cells be counted using a Coulter Counter or an Elzone particle counter and that the count for viability (determined by trypan blue exclusion and a hemacytometer; *APPENDIX 3C* be corrected on the basis of the automated cell count to determine the viable cell density).

B. C. U. „M... IAŞI

BCU IAŞI / CENTRAL UNIVERSITY LIBRARY

Materials

Cells expressing gene product of interest (see Basic Protocol 3 or Alternate Protocol 1) growing in tissue culture flasks or dishes at 70% to 90% confluency
Appropriate culture medium

Coulter Counter or equivalent
96-well tissue culture plates

Additional reagents and equipment for growing mammalian cells in culture, trypsinizing cells, and counting viable cells by trypan blue exclusion (*APPENDIX 3C*)

1. Trypsinize cells (*APPENDIX 3C*). Break up any cell clumps by pipetting up and down repeatedly, then count cells using a Coulter Counter and determine number of viable cells by trypan blue exclusion.

2a. *Cloning method 1:* Resuspend cells in fresh medium at a concentration such that there will be 0.3 to 1.0 cell per well of a 96-well plate, in 200 to 250 µl of medium per well. Pipet a 200- to 250-µl aliquot of this suspension into each well.

2b. *Cloning method 2 (visual check):* Resuspend in medium at a concentration of 1 cell per 5 to 10 µl medium. Place a 5- to 10-µl drop (a Pasteur pipet can be used for this purpose) in center of flat-bottom 96-well tissue culture plate. Observe ~5 wells at time under an inverted microscope at 100× to 200× magnification, then add 200 to 250 µl of medium to wells with only a single cell.

3. Incubate, replacing medium once every 1 to 2 weeks.

Large colonies with at least 2000 cells take ~2 to 4 weeks to form.

BASIC PROTOCOL 4

AMPLIFICATION OF DIHYDROFOLATE REDUCTASE (DHFR) WITH METHOTREXATE (MTX)

The level of expression after selection is usually not sufficient when the goal is to create a cell line for the production of the protein on a large scale. Amplification to increase gene dosage is a method for creating high producers. Cells are allowed to adapt to growth in the presence of a drug that inhibits the activity of the selection marker. This adaptation usually results from an increase in gene copy number to overcome the inhibition. Stepwise increases in drug concentration and adaptation of the cells amplify the cell line. In this protocol, the selection marker used is dihydrofolate reductase and the drug that stoichiometrically binds and inhibits DHFR activity is methotrexate (MTX). The glutamine synthetase marker and its corresponding inhibiting drug, methionine sulfoximine, is another amplification system that can be used with CHO cells.

Materials

Culture of transformed cells at 50% to 70% confluency, in T-25 or T-75 flasks (24 to 48 hr post-transfection; see Basic Protocol 2 or Alternate Protocol 1)
Nucleoside-free αMEM medium (see recipe but omit nucleosides) containing 10% FBS that has been dialyzed to remove nucleosides (HyClone)
10 mM methotrexate (MTX) stock solution (Sigma; store up to 1 year at –20°C; thaw just before use)

96-well flat-bottom tissue culture plates
24-well tissue culture plates
T-25 tissue culture flasks
100-mm tissue culture dishes

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Additional reagents and equipment for growing mammalian cells in culture, trypsinizing cells, and counting viable cells by trypan blue exclusion (*APPENDIX 3C*)

Perform selection

1. At 24 to 48 hr post-transfection, harvest cells by trypsinization and determine number of viable cells by trypan blue exclusion (*APPENDIX 3C*).
2. Plate 100 to 1000 cells in each well of a 96-well tissue culture plate using 200-µl ml nucleoside-free αMEM/10% dialyzed FBS per well. Begin incubation.
3. As colonies grow and become confluent, screen clones (see Basic Protocol 3, step 4).
4. Trypsinize viable productive colonies and transfer to wells of a 24-well plate, each containing 2 ml nucleoside-free αMEM/10% dialyzed FBS. After cells reach confluency, trypsinize and transfer half to inoculate T-25 flasks containing 5 to 10 ml nucleoside-free αMEM/10% dialyzed FBS. Combine the remaining cells from all clones into one single pool and use in step 5.

   The clones transferred to the T-25 flasks can undergo selection.

   Screening is recommended at this stage before starting the amplification process.

Perform first round of amplification

5. Plate pooled cells at a density of 0.6–1.2 × 10^6 cells/ml in nucleoside-free αMEM/10% dialysed FBS (selective medium) containing 0.02, 0.05, 0.1, and 0.2 µm MTX (added from 10 mM stock) in a series of 100-mm dishes.
6. Replace selective medium in each dish with selective medium containing the same MTX concentration every 3 to 4 days and observe cells using an inverted microscope to monitor cell death and detachment.

   Large colonies of live cells (containing 100 to 200 cells) should appear within 3 weeks.

7. Trypsinize cells and count number of viable cells by trypan blue exclusion (*APPENDIX 3C*).
8. Plate cells from each of the methotrexate concentrations in wells of the same 96-well tissue culture plate at 0.3 to 1.0 viable cells per well in 200 µl selective medium with same MTX concentration as used before. Incubate until confluent, then transfer to 24-well plates and screen clones for productivity (see Basic Protocol 3, step 4).

Perform additional rounds of amplification

9. Plate remaining cells from step 7 at a density of 0.6–1.2 × 10^6 cells per 100-mm dish in selective medium containing an MTX concentration 2- to 5-fold higher than that used before (0.5, 1, 2, 5, and 10 µM MTX).
10. After cells are adapted to the next level of methotrexate carry on with steps 7 to 9.

BCU IAST / CENTRAL UNIVERSITY LIBRARY

ADAPTATION OF SUSPENSION CELLS TO PRODUCTION MEDIUM THROUGH MULTIPLE PASSAGING

Adaptation of transfected CHO cell lines to suspension growth is recommended to enable growth in spinner bottles or reactors. Suspension growth in low-serum medium may improve the initial specific purity of the product by providing the opportunity for higher cell density and product titer than can be obtained by surface-attachment growth, as well as by reducing serum proteins in the medium. Growth of cells in suspension, in medium containing adequate levels of nutrients, enables use of compact production systems in which high cell density can be achieved. Such compact systems are economical choices in laboratory environments.

Materials

Mid–log phase culture of stable-transfected cells in T-75 flask (or thawed 1-ml aliquot of cryopreserved cells; see Support Protocol 2), produced by DHFR selection/MTX amplification (see Basic Protocol 4) or other selection/amplification procedure

Nucleoside-free αMEM medium (see recipe but omit nucleosides) containing 10% FBS that has been dialyzed to remove nucleosides (for DHFR selection/MTX amplification cells) *or* regular αMEM medium (see recipe) containing 10% FBS (prepare as appropriate for cells produced by other selection/amplification procedures)

10 mM methotrexate (MTX) stock solution (Sigma; store up to 1 year at –20°C; thaw just before use)

Dispase solution (Boehringer Mannheim)

DMEM/F12 custom-modified medium (see recipe) with 10%, 1%, and 0.5% dialyzed FBS

CD CHO medium (for DHFR systems; Life Technologies), Super CHO (for non-DHFR systems; Bio-Whittaker), or CHO-S-SFM (for non-DHFR systems; Life Technologies)—optional, for adaptation to serum-free medium

1 g/liter Nucellin-Zn salt (recombinant insulin; Eli Lilly)—optional, for adaptation to serum-free medium

T-175 flasks

Sterile 45-ml polycarbonate screw-cap tubes

Inverted phase-contrast microscope

250-ml shaker flasks

Platform shaker (New Brunswick Scientific)

Additional reagents and equipment for growing mammalian cells in culture, trypsinizing cells, and counting viable cells by trypan blue exclusion (*APPENDIX 3C*), determining specific growth rate of cells (see Support Protocols 4, 5, and 9), determining specific productivity of cells producing heterologous protein (see Support Protocols 6 and 7), and freezing cells (see Support Protocol 2)

Establish cultures in adaptive medium

1. Preincubate a T-175 flask and add 50 ml of prewarmed fresh αMEM/10% FBS (nucleoside-free and containing MTX concentration used for amplification if produced via Basic Protocol 4; prepare as appropriate for other selection/amplification schemes). Keep flask in incubator until the inoculum is prepared.
2. Remove the medium from a mid–log phase (50% to 90% confluent) T-75 flask of stable-transfected cells using a sterile 25-ml pipet. Trypsinize and harvest the cells into a sterile 45-ml polycarbonate tube (*APPENDIX 3C*).

FCU IASI / CENTRAL UNIVERSITY LIBRARY

flask into a shaker flask to begin suspension adaptation, the starting cell density for the new culture should be ~1 × 10^5 viable cells/ml. The procedures for trypsinizing and passaging cells are described in APPENDIX 3C.

3. Determine the concentration of viable cells by trypan blue exclusion (*APPENDIX 3C*), or, if clumping is evident, by adding 0.3 to 2.4 U/ml dispase, incubating 15 min at 37°C, then counting the number of viable cells by trypan blue exclusion. From the viable cell concentration determine the volume of suspension to inoculate into a T-175 flask to obtain a concentration of 1×10^4 viable cells/cm^2. Add the required volume of inoculum to the T-175 flask and incubate.

   CHO cells have a tendency to clump when grown at high cell density in the higher-serum medium. Clumping may be minimized by adapting cells to growth in lower serum (≤0.5% FBS). Reduced-calcium media such as DMEM/F12 also may produce less cell clumping. In cultures that contain clumping cells the only secure counting method is through use of dispase before hemacytometer/trypan blue counting.

4. Periodically observe cells in the tissue culture flask using an inverted phase-contrast microscope at 125× magnification. When the cells reach a confluency of 50%, remove the spent medium and replace with the new medium, DMEM/F12 supplemented with 10% dialyzed FBS and the concentration of MTX (or other selective agent) used previously. Continue incubation, periodically observing growth using the inverted microscope.

5. When cells reach 80% to 95% confluency, trypsinize and harvest the cells. Determine the viable cell density (*APPENDIX 3C*) and calculate the volume of inoculum required to give a final concentration of 1×10^5 viable cells/ml in 100 ml. Simultaneously, prepare a 250-ml shaker flask with 100 ml of fresh DMEM/F12/10% dialyzed FBS/MTX and preincubate to 37°C.

6. Remove the volume of medium calculated for the inoculum from the shaker flask and transfer the corresponding volume of inoculum. Mix by gentle swirling, then remove a 0.25-ml sample and determine post-inoculation viable cell density (*APPENDIX 3C*). Loosely cap the flask, and begin incubation with agitation at 75 to 125 rpm on a platform shaker.

7. Continue incubation and calculate specific growth rate from the growth curve (see Support Protocols 4, 5, and 9) and specific productivity (see Support Protocols 6 and 7). Determine the viable cell density (*APPENDIX 3C*) daily. At 4 days post inoculation, or when the cell density has reached 4×10^5 viable cells/ml, transfer sufficient cells to inoculate a second passage flask as in step 6.

8. Passage the cells in changes of the same medium until the passage-specific growth rate reaches a constant maximum value. At this passage, reduce the serum concentration in the medium to 1% dialyzed FBS.

   Also ascertain that the specific productivity remains within reasonable bounds with increased passage number, as an indication of expression stability.

9. When the passage-specific growth rate shows no further increase, reduce the serum to 0.5% and repeat adaptation passaging.

   When growth rate shows no further gain, the cells have adapted to the low level of serum.

Confirm adaptation to production medium

10. Confirm that cells have adapted to the low level of serum by splitting the cells into two flasks: one with medium plus 10% FBS and another with medium plus 0.5% FBS. Determine growth rate, which show no large difference for correctly adapted cells.

BOLTON CENTRAL UNIVERSITY LIBRARY

11. *If serum-free growth is desired:* Perform a further adaptation from 0.5% to 0% serum by repeating the adaptation steps through a final round using specific-protein-free medium such as CD CHO, Super CHO or CHO-S-SFM (or equivalent). Supplement with 5 mg/liter of Nucellin (added from 1 g/liter stock) and reduce to 1 mg/liter gradually

12. Freeze adapted cells (see Support Protocol 2) or proceed to growth in batch mode (see Basic Protocol 6).

BASIC PROTOCOL 6

GROWTH OF CELLS IN BATCH MODE IN LARGE-SCALE SPINNER CULTURE VESSELS

Suspension-adapted cells may be grown in spinner flasks accommodating liquid volumes of up to 16 liters. Flasks are placed in a humidified temperature-controlled environment, which contains 5% CO_2 gas. The CO_2 is used to provide dissolved carbon dioxide and bicarbonate, which provide nutrient substrate and buffer components in the culture medium. The flasks are set on a rotating platform to agitate the liquid surface and provide adequate oxygen transfer to support cell oxygen demand. The procedure may be initiated from a vial of the cells or from ongoing shaker flasks that are being passaged (see Basic Protocol 5). The ultimate scale of production depends on the expression level, the purification yield, and the quantity of protein required by the researcher. Flasks can accommodate up to 100 ml of culture while small glass spinner jars can be used to produce up to 3 liters of culture. When larger volumes of liquid culture are required, the spinner flasks may become more complicated in design, including dissolved oxygen (dO_2) controllers and pH controllers. Volumes greater than 5 liters of culture can be obtained by using 20-liter spinner jars.

The increased volume and subsequent apparatus size becomes cumbersome and is worthy of arranging in a fixed location. In order to supply adequate oxygen to support the cultures, it is necessary to set up such a spinner jar in a warm room or with an external wraparound band heater (Watlow). The spinner jar is usually fitted with a top-entry mechanical stirrer (Bellco Biotechnology). The supply of oxygen to the culture is achieved through sparging with O_2/air mixtures through a sparge tube fitted with a frit (Mott Cups) and by adding a CO_2/O_2/air mixture into the headspace. Similarly the control of pH is best achieved through use of an in-vessel pH probe with adjustment by addition of 0.5 M NaOH using automatic pH controllers or manually performing daily pH checks. A typical large volume (20-liter) spinner set up is shown in Figure 5.10.2.

Here continued use of MTX is desired, use nucleoside-free medium and dialyzed FBS. In most cases where stable integration and production has been acceptable at levels <1 μM MTX, the continued use of methotrexate should not be required.

Materials

1-ml cryovial or mid–log phase culture of suspension-adapted cells (see Basic Protocol 5)
Medium to which cells have been adapted (see Basic Protocol 5), supplemented with 4 mM L-glutamine and 4.5 to 5.5 g/liter D-glucose
Medical-grade, sterile-filtered 5% CO_2/air mixture
Medical-grade, sterile-filtered 100% O_2 (if necessary)

250-ml screw-cap shaker flasks
Platform shaker (New Brunswick Scientific)
1-, 5-, and 20-liter borosilicate glass spinner jars (Bellco Biotechnology)
Flat-plate stirrer platform (Bellco Biotechnology)

RCU IASI CENTRAL UNIVERSITY LIBRARY

Peristaltic pump (head size 15, 16, 24; with 0 to 600 rpm capability; Watson-Marlow or Cole-Parmer)
Sterile silicone tubing (Pt-cured; size 15, 16, 24; Masterflex from Cole-Parmer)
Sterile 50-ml syringes
Dissolved oxygen probe (Ingold)
pH probe (Ingold or Broadley James)

Additional reagents and equipment for growing mammalian cells in culture and counting viable cells by trypan blue exclusion (*APPENDIX 3C*), determining specific growth rate of cells (see Support Protocols 4, 5, and 9), and determining specific productivity of cells producing heterologous protein (see Support Protocols 6 and 7)

Establish cultures

1. Thaw a 1-ml cryovial of the culture in a 37 ± 1°C water bath for ~2 min with gentle shaking.
2. To a 250-ml screw-cap shaker flask, add a volume of cells from the vial sufficient to inoculate 100 ml of the medium to which the cells have been adapted (supplemented with L-glutamine and D-glucose and prewarmed to 37°C), at 1×10^5 viable cells/ml.

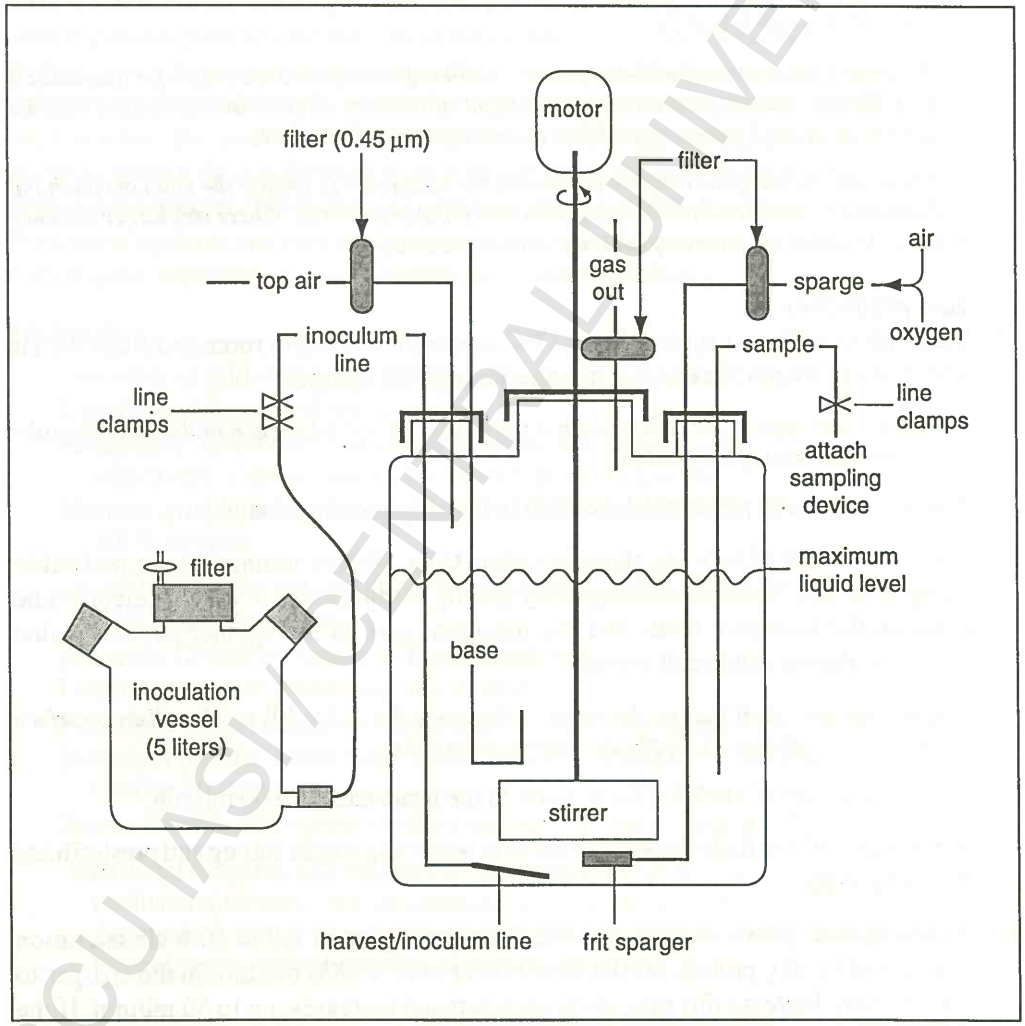

Figure 5.10.2 Typical arrangement of 20-liter spinner jar for batch cell culture.

BCU IASI / CENTRAL UNIVERSITY LIBRARY

Incubate flask in a humidified 37°C ± 0.5°C, 5% CO_2 incubator with rotation at 100 rpm on a platform shaker. Measure the viable cell density daily (*APPENDIX 3C*).

When the culture reaches mid–log phase (~3 to 4 days) the cells are suitable for inoculation of a 1-liter spinner jar containing 400 ml medium.

Inoculate spinner jar cultures

3. Add 400 ml of 37°C medium to a preincubated (5% CO_2, 37°C) 1-liter glass spinner jar. Add 100 ml of the mid–log phase shaker flask culture through the side arm. Determine the post-inoculation viable cell density, then place the spinner jar in the incubator on a flat-plate stirrer platform and set the stirrer speed to 60 to 80 rpm. Incubate, measuring the viable cell density daily.

   When the culture reaches mid–log phase (~3 to 4 days) the cells are suitable for inoculation of a 5-liter spinner jar containing 1600 ml of medium. The culture may be continued in the 400-ml spinner culture by adding glucose to a final concentration of 2 g/liter and glutamine to a final concentration of 2 mM on days 4, 6, and 8, along with daily pH monitoring and adjustment to 7.0 to 7.4 using 0.5 N NaOH.

4. Add 1600 ml of 37°C medium to a preincubated 5-liter glass spinner jar. Add the 400 ml of the mid–log phase culture. Determine the post-inoculation viable cell density and incubate with stirring as in step 3. Measure the viable cell density daily and monitor growth rate (see Support Protocols 4, 5, and 9) and specific productivity (see Support Protocols 6 and 7).

   When the culture reaches mid–log phase (~3 to 4 days) the cells are suitable for inoculation of a 20-liter spinner jar containing 4500 ml of medium. Otherwise the culture may be continued in the 5-liter jar by adding nutrients as described above.

   Knowledge of the growth curve will enable the researcher to choose the point at which the cells may be harvested with adequate viability and cell density. Where still larger volumes up to 16 liters are required, continue with step 5 onwards.

Increase production

5. Preincubate a 20-liter spinner jar at 37°C overnight in a warm room and flush the jar with filtered sterile 5% CO_2/air mixture through the sparger.

   The 20-liter spinner jar is fitted with a sterilizable dissolved oxygen probe and pH probe for measurement of dO_2 and pH.

6. Add 4.5 liter fresh prewarmed medium to the empty preincubated jar.

7. Transfer 1.5 liter of mid–log phase inoculum to the 20-liter spinner using a peristaltic pump with size 16 silicone tubing or by gravity feeding using a size 16 silicone tube between the inoculum bottle and the inoculum port on the spinner jar. Determine post-inoculation viable cell density.

   After inoculation, if the cell density is in the range 0.5–1.5 × 10^5 viable cells/ml, surface aeration is sufficient to supply the oxygen to the cells.

8. Set the flow rate of air/5% CO_2 mixture in the headspace to 100 ml/min.

9. Sample the culture daily through a side-arm port using sterile tubing and presterilized 50-ml syringes.

10. As the culture grows, and the dissolved oxygen begins to fall to 50% air saturation (measured by dO_2 probe), set the flow rate of air/5% CO_2 mixture in the sparger to ~25 ml/min. Increase this rate, as oxygen demand increases, up to 50 ml/min. If the demand for oxygen is not met (i.e., if the dO_2 remains <50% of saturation) using the air/5% CO_2 mixture, add 100% oxygen to the mixture. Maintain the dissolved oxygen

ECU IASI CENTRAL UNIVERSITY LIBRARY

between 20% and 100% air saturation. Maintain pH in the range 7.2 to 7.4 using automatic pH control or daily manual addition of 0.5 N NaOH.

11. When the culture reaches mid–log phase (around day 4) add 6 liters of fresh prewarmed (37°C) medium using a peristaltic pump and size 16 silicone tubing (see step 7).

12. When the 12-liter culture reaches mid–log phase (around day 6) add 4 liters of fresh prewarmed (37°C) medium.

The 16-liter culture may be grown up to the desired point for harvesting or may be operated in a feed-and-bleed mode. In feed-and-bleed mode, typically 4 to 10 liters of medium can be harvested from the late log-phase culture and replaced with the equivalent volume of fresh medium.

13. Harvest the protein product (see Basic Protocols 8 and 9).

GROWTH OF CELLS IN LARGE-SCALE BATCH REACTORS

BASIC PROTOCOL 7

Stirred-tank bioreactors may range in scale from 10 liters to 200 liters in a laboratory/pilot plant location. Bioreactors are distinguished from glass jar spinners and similar devices by their robust stainless-steel design and automatic control systems for temperature, dissolved oxygen, and pH, as well as instrumentation for monitoring important parameters such as medium flow rate, gas flow rate, pressure, weight, and liquid level. Bioreactors should possess ports around the base of the vessel for insertion of pH and dissolved oxygen probes. Since bioreactors may contain large volumes of culture and may operate at high cell density, the total oxygen demand is larger than can be supplied by agitation alone. In such reactors the addition of oxygen is achieved through sparging of the culture. This involves adding the gas through a frit-type device at the base of the reactor, or through a drilled-hole sparger. The authors recommend the frit design for reactors up to 500 liters. Bioreactor systems are supplied by specialized manufacturers of process equipment and may require lead time of 3 to 6 months from order to delivery.

Materials

Inoculum of mid–log phase cells in spinner jar (see Basic Protocol 6)
Ultrafiltered deionized water
Medium to which cells have been adapted (see Basic Protocol 5), supplemented with 8 mM L-glutamine and 4.5 to 5.5 g/liter D-glucose
Medical-grade, sterile-filtered 95% N_2/5% CO_2 and 95% air/5% CO_2 mixtures and 100% oxygen
10- to 100-liter bioreactor (New Brunswick Scientific, Bioengineering, Braun, New MBR, Applikon)
pH probe (Broadley James or Ingold), calibrated
Dissolved oxygen probe (Ingold), pretested
Autoclave large enough to accommodate bioreactor vessel (Finn Aqua)
Inoculum transfer bottle with bottom side port attached to sterile size 16 tubing (Bellco Biotechnology)
Sterile flexible disposable medium and harvest bags (Stedim Laboratories)
Additional reagents and equipment for counting viable cells by trypan blue exclusion (*APPENDIX 3C*), determining specific growth rate of cells (see Support Protocols 4, 5 and 9) and determining specific productivity of cells producing heterologous protein (see Support Protocols 6 and 7)

BOSTON UNIVERSITY CENTRAL LIBRARY

Prepare the bioreactor assembly

1. Assemble bioreactor components—e.g., agitator, sparger lines, outlet gas line, top headspace gas inlet, base addition lines, medium addition lines, inoculum transfer lines, harvest lines, and sample port lines.

   Recommended equipment includes sterile tubing (Pharmed) and connection tubing welder SCD IIB (Terumo Medical).

2. Prepare an inoculum for inoculation of the bioreactor.

   This would be between 0.1 and 0.15 liter of mid–log phase culture per liter of bioreactor operating volume. For a 100-liter bioreactor, an inoculum volume of 10 to 15 liters is required and would be produced by the 20-liter spinner method (see Basic Protocol 6).

3. Calibrate the pH probe and insert into reactor through the side port. Insert the pretested dissolved oxygen probe. Fill the vessel with ultrafiltered deionized (UFDI) water to cover the probes if sterilization is not immediately scheduled. Prior to sterilization, remove water.

4. Add ~10 ml ultrafiltered deionized water per liter of vessel volume and sterilize the vessel in an autoclave for 1 hr at 121°C, using slow exhaust for cooling phase.

5. Pump the culture medium into the vessel to cover the probes. Equilibrate system by sparging the medium and headspace at ~0.005 vessel liquid volumes per minute with a 95% N_2/5% CO_2 mixture, and allow the medium to reach the 37°C operation temperature. After equilibration (~5 hr required) is complete (as judged by an *x*-axis asymptotic dissolved oxygen trace), set the dissolved oxygen probe to 0% air saturation, then sparge the vessel with 95% air/5% CO_2 mixture. After equilibration, set the dissolved oxygen probe span to 95% air saturation.

   Optional recommended equipment includes a YSI 2700 Select glucose, glutamine, and lactate analyzer (YSI Instruments) and an IBI Biolyzer for ammonia and lactate (Kodak Lab Research Products).

Inoculate the bioreactor

6. Adjust the medium volume to 40% of the target final harvest volume (e.g., 4 liters in a 10-liter-operating-volume vessel). Equilibrate to 37°C, then inoculate to a starting density of 1 to 2×10^5 viable cells/ml using the inoculum transfer bottle.

7. Set the sparge air-flow rate to ~0.005 vessel volumes of air per vessel liquid volume and set the dissolved oxygen controller to add pure (100%) oxygen to the sparger on demand. Purge the headspace 0.0025 vessel liquid volumes of air. Agitate the culture at an rpm producing a tip speed of 1000 to 1500 cm/sec.

8. Continue incubation, determining the post-inoculation viable cell density daily (*APPENDIX 3C*). Monitor growth rate of cells

9. Feed medium beginning on day 2 and adjust the rate daily to give a rate of 2 liters per day per 1×10^9 total viable cells until the target volume is reached. At that point, stop feeding fresh medium.

10. During the initial-feed batch and final batch phases maintain the pH in the range 7.2 ± 0.1, the temperature at 37°C ± 0.5°C, and the dissolved oxygen in the range of 20% to 100% air saturation.

    The feed rates can be set through use of precalibrated pumps and checked using load cells that measure the medium supply container weights.

11. Harvest the protein product (see Basic Protocols 8 and 9) using a sterile flexible bag.

FCU IASI / CENTRAL UNIVERSITY LIBRARY

GROWTH OF CELLS IN CONTINUOUS CULTURE IN BIOREACTORS

Continuous culture refers to the operation of a bioreactor where the cells are removed at a particular rate and replaced with fresh medium at an equal rate. The ratio of the medium-addition rate to the culture volume is known as the dilution rate. Continuous culture may be desirable where large quantities of protein product are required for further studies, and is also of interest to the researcher for examining the potential effects of growth rate on the product. In this situation, a continuous reactor is set up with no cell retention devices. Where the researcher wishes to maximize the productivity of the given system, a continuous perfusion (cell retention) system would be used. Medium is removed at a rate corresponding to the addition rate of fresh medium but a large proportion of cells are retained in the reactor through use of suitable retention devices. The retention devices are usually either internal spin filters (supplied with bioreactors), external tangential cross-flow microporous filtration devices (Millipore, A/G Tech, Sartorius, Pall-Filtron) with cell recycle, external centrifugal devices (Centritech from Sorvall) with cell retention, or inclined settling surfaces (custom designed), which may be internal or external. Recently acoustic settlers have become available (Sonosep) and these are possible candidates for bioreactor scales around 10 to 30 liters.

The reactor assembly would incorporate the required peripherals for continuous operation (Fig. 5.10.3). In the case of perfusion, the settling device would be incorporated and sterilized along with the bioreactor. The basic setup is the same as described previously (see Basic Protocol 7).

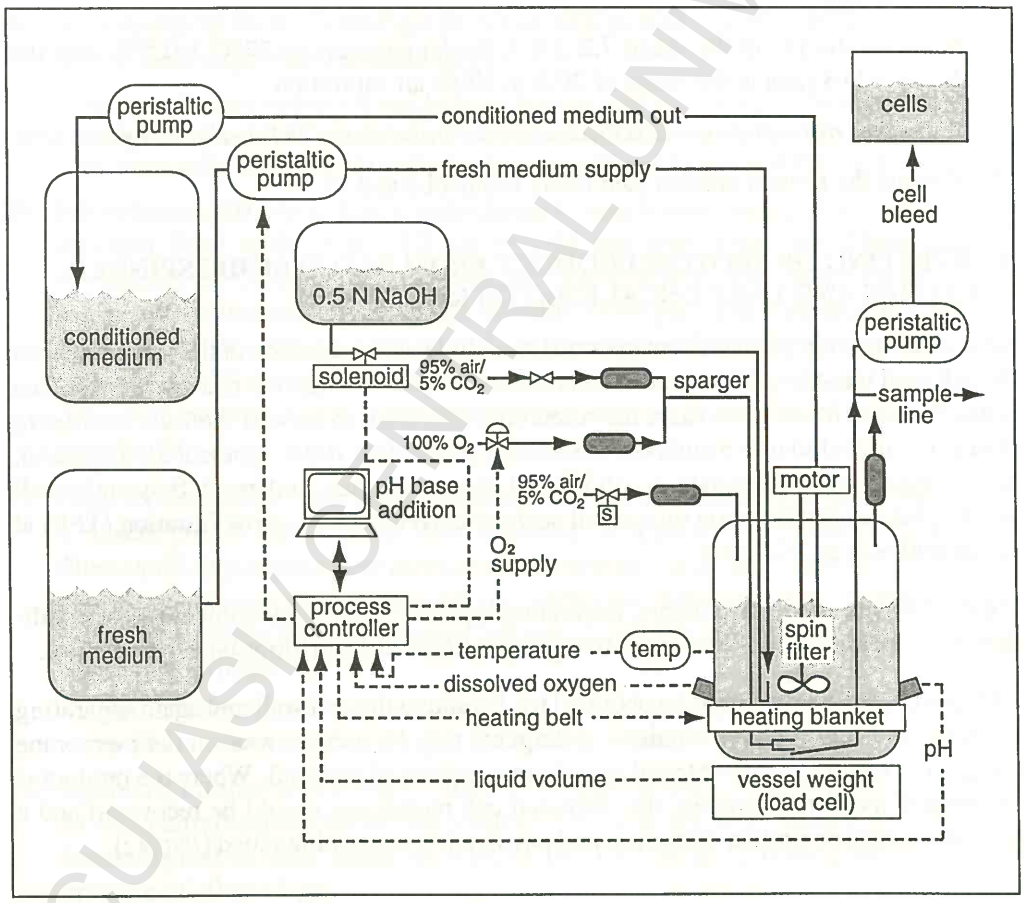

Figure 5.10.3 Compact-scale perfusion cell culture system. Shows typical connection of medium and product tanks to compact (100-liter) reactor. Simple pH, dissolved oxygen, and vessel weight control loops are illustrated. Medium and product vessels (for conditioned medium and/or cells) should be set up in a cold-box environment.

CU IASU CENTRAL UNIVERSITY LIBRARY

Additional Materials (also see Basic Protocol 7)

Bioreactor with accessories for continuous operation (consult New Brunswick Scientific, New MBR, Bioengineering AG, Braun, or other fermenter manufacturer; for perfusion operation where retention is required, use reactors with spin filter design, e.g., New MBR or Braun)

Sterile bags (Stedim Laboratories) or sterilized stainless steel containers for collection of medium

1. Set up and inoculate bioreactor (see Basic Protocol 7, steps 1 to 7). For the simple continuous mode and perfusion operation, feed medium at a rate of 2 liters per day per 1×10^9 total viable cells, up to the total operating volume of the reactor.

2. When the cells have reached mid to late log phase, begin cell removal at the target rate corresponding to the desired dilution rate (the volume of medium added to the vessel per day per reactor operating volume)

   The reactor operating volume is constant with respect to time. Fresh medium is fed to the reactor to maintain constant volume. In the case of the perfusion reactor, the retention device results in cells being returned to the bioreactor medium, and the cell density increases until it becomes limited by a nutrient or by toxic waste products such as ammonia and lactate. At that point a steady-state condition will be reached and cell density will remain constant.

3. Collect the conditioned medium as it removed from the bioreactor in sterile bags or sterilized stainless steel containers. Cool the stream to 4° to 8°C to minimize product degradation.

4. Maintain the pH in the range 7.2 ± 0.1, the temperature at 37°C ± 0.5°C, and the dissolved oxygen in the range of 20% to 100% air saturation.

   The feed rates can be set through use of precalibrated pumps and checked using load cells.

5. Harvest the protein product (see Basic Protocol 8 and 9).

HARVESTING OF PROTEIN PRODUCT FROM BATCH MODE SPINNER CULTURES AND LARGE-SCALE BATCH REACTORS

Most often, protein production in mammalian cells leads to secretion of the product across the cell wall into the culture medium where it accumulates with time in a batch mode (see Basic Protocol 8). In some cases the researcher may wish to harvest the cells in order to obtain an intracellular or membrane-associated protein (see Basic Protocol 9). In general, all strategies will necessitate a solid/liquid separation step and most frequently will employ batch centrifugation on a small scale or tangential cross-flow filtration (TFF) at larger scales, e.g., ≥20 liters.

For continuous-mode bioreactors, harvesting typically involves accumulation of conditioned medium, which is processed using depth filters and ultrfiltration concentration.

Cell-associated product must be obtained by disrupting the cell wall and again separating the solid and liquid phase. Nonionic detergents may be used to weaken the membrane and aid the release of non–integral-membrane–associated material. Where the product is an integral membrane protein, the disrupted cell membrane should be recovered and a typical membrane protein extraction and purification protocol pursued (*UNIT 4.2*).

PCU IAST / CENTRAL UNIVERSITY LIBRARY

Harvesting a Secreted Product

Materials

Cells in batch culture (see Basic Protocols 6 or 7 or Alternate Protocol 3)
Phosphate-buffered saline (PBS; *APPENDIX 2E*)
TE buffer or PBS (*APPENDIX 2E*)

Sterile bags (Stedim Laboratories)
Refrigerated centrifuge: Sorvall RC-5B or RC-3B, Beckman J2-21 or S600, or equivalent
Microfiltration system with membranes for cell concentration and debris/product separation (Sartorius, Pall-Filtron, or Millipore)
Depth filtration membranes for large-scale debris separation prior to sterile filtration (Cuno Bio-Cap 90 SP or equivalent products from Millipore or Sartorius)
Filter-sterilizing capsules (0.2-μm membrane; Sartorius, Pall, or Millipore)
Silicone tubing, autoclaved
Sterile polycarbonate containers
Ultrafiltration system with membranes for protein concentration (MWCO 10-kDa; Sartorius, Pall-Filtron, or Millipore)

1. Following completion of the batch process in spinner jar or a bioreactor remove medium from the reactor harvest port using sterile silicone tubing and a peristaltic pump. Collect into a sterile container such as a presterilized glass jar or sterile disposable plastic flexible bag. Chill collected material to 4° to 10°C

2a. *For volumes ≤6 liters:* Centrifuge 10 min at 1000 to 4000 × *g*, 4° to 10°C, in a Sorvall RC-3B centrifuge with standard rotors.

For up to 20-liter volumes it may be feasible to use a larger-capacity laboratory centrifuge such as the Sorvall RC-5B fitted with the swinging bucket rotor accommodating six 1-liter buckets; using this setup the cells should be centrifuged 15 min at 4000 × g, 4° to 10°C.

2b. *For volumes >20 liters:* Use a wide-channel nonscreened microporous cross-filtration unit fitted with ~1 ft^2 (0.2 μm or 0.45 μm pore rating) per 2-liter culture. Recirculate the cells through the retentate loop to give an inlet gauge pressure ≤10 psi. Limit the transmembrane gauge pressure to <4 psi using a peristaltic pump on the permeate line. Concentrate the cells in the retained filter stream by reducing the volume 10-fold, then permeate a further 3 vol PBS to wash the cells and recover the remaining product. Collect and chill the permeate in sterile plastic bags or sterile containers.

3. Filter the centrifuge supernatant, perfusion conditioned medium, or permeates using a rinsed, prewet liquid depth filter followed by a prewet or rinsed 0.2-μm rated filter-sterilizing capsule. Use autoclaved silicone tubing on the sterile side of the filter capsule and recover product in sterile polycarbonate containers or sterile plastic bags. Rinse the capsules with a minimum amount (50 to 100 ml) of TE buffer or PBS to recover the product.

IMPORTANT NOTE: *It is very important to prewet or rinse capsule filters as they hold significant amounts of liquid, which can result in a loss of product.*

4. *Optional:* Further concentrate filtrate by tangential ultrafiltration using a 10-KDa MWCO ultrafiltration membrane sized to 1 ft^2 of screened membrane per 20 liters. Recirculate at an inlet gauge pressure of 20 to 30 psi and a transmembrane gauge pressure of 10 to 15 psi.

A minimum recirculation loop volume of 100 ml is feasible for small-scale systems (Millipore, Sartorius, or Filtron Slice units) and will define the maximum physical concentration factor.

BOURKE UNIVERSITY LIBRARY

5. Rinse the filtration loop and filters with 50 to 100 ml of TE buffer or PBS to recover the product.

The product may be purified directly or stored frozen (see Support Protocol 3) until required.

BASIC PROTOCOL 9

Harvesting a Cell-Associated Product

Materials

Cells in batch culture (see Basic Protocols 6 or 7 or Alternate Protocol 3)
Phosphate-buffered saline (PBS; *APPENDIX 2E*)
Homogenization buffer (see recipe), 4°C
Cell homogenizer: e.g., Microfluidizer (Microfluidics), Tissumizer (Tekmar-Dohrmann), Dounce homogenizer (Bellco Biotechnology), or Manton-Gaulin-APV homogenizer (APV-Gaulin)

Additional reagents and equipment for centrifugation or cross-flow microfiltration of cell suspension (see Basic Protocol 8)

1. Subject cell suspension from batch culture to centrifugation or cross-flow microfiltration (see Basic Protocol 8, steps 2a or 2b), but retain centrifuge pellets or cross-flow filtration–concentrated slurry. Keep cells at 4° to 10°C.
2. Resuspend cells in 3 to 5 vol PBS (or other isotonic buffer) and centrifuge 10 min at 1000 to 4000 × *g*, 4° to 10°C.

   The cell pellet may be stored frozen (<–35°C) or processed directly.

3. Resuspend pellet in 2 to 3 vol of 4°C homogenization buffer. Lyse cells using a tissue homogenizer at 4°C.

   For larger volumes, it is possible to recirculate the suspension through a gear-type pump at high flow rate (obtain 10-20 psig pump outlet pressure in a 0.25-0.5 in.-diameter tube recirculation loop).

4a. *For volumes <20 liters:* Centrifuge the homogenate 30 min at 5000 × *g*, 4°C to remove the bulk of the debris. Filter sterilize the supernatant, which will contain the released soluble protein, prior to storage or further processing.

4b. *For large volumes:* Remove the debris using microfiltration/tangential-flow filtration (MF-TFF) at an inlet gauge pressure of 20 psi and limit the transmembrane gauge pressure to <4 psi using a peristaltic pump on the permeate line. Wash the retained concentrated debris with 3 to 5 vol buffer. Filter-sterilize the permeate, which will contain the released soluble protein, prior to storage or further processing.

Cell debris containing integral membrane protein may be recovered as the retentate concentrated slurry.

The permeate stream may be concentrated using cross-flow ultrafiltration, as described for secreted protein (see Basic Protocol 8).

PCU IASI / CENTRAL UNIVERSITY LIBRARY

FREEZING CELLS FOR PRODUCTION OF CELL BANKS

In order to be able to produce recombinant proteins consistently from batch to batch, it is advisable to produce a number of equivalent storage vials of the cell line—often referred to as a parent or master cell bank. Before attempting large-scale culture with a new cell bank the researcher is strongly advised to ensure that the cell bank is not contaminated by microbes, including mycoplasma, and that it grows normally (i.e., compared to the growth curve obtained during preparation). A growth curve test of the vial would detect contamination by bacteria, yeast, and fungi, while mycoplasma may be determined using commercial kits such as the Fluorescent DNA stain (Hoechst). A primary cell bank, or parent or master cell bank (MCB), can be used as the source to create subsequent working cell banks (MWCB) when necessary, depending on the scale of production. General principles and procedures for cryopreservation of attachment-dependent cells are provided in *APPENDIX 3C*. The following protocol is applicable to cells that have been adapted for suspension growth.

Materials

High-viability (>95%) log-phase culture of cells
Freezing medium: complete medium used for growing cells supplemented with 10% to 20% (v/v) FBS and 5% to 10% (v/v) DMSO (Sigma), 4°C

45-ml sterile screw-cap tubes polycarbonate centrifuge tubes (Falcon from Becton Dickinson)
Sorvall T-6000B centrifuge (DuPont) or equivalent
1.5-ml Nalgene cryotubes (Nunc)

Additional reagents and equipment for counting viable cells by trypan blue exclusion (*APPENDIX 3C*)

1. Take an aliquot of ~1 ml from a high-viability log-phase culture and determine the viable cell density (*APPENDIX 3C*). Determine the number of vials to be produced, then, based on the viable cell density and the total number of frozen vials to be prepared for the cell bank, calculate the volume of suspension culture needed.

   Each vial should usually contain 0.5 or 1×10^7 viable cells with a density of 1×10^7 cells/ml.

2. Transfer the desired volume of cell suspension to one or more sterile 45-ml polycarbonate centrifuge tubes and centrifuge 10 min at 300 to 350 × *g* in a T-6000B or equivalent centrifuge, room temperature.

3. Decant supernatant from the centrifuge tube(s) and resuspend pellet in required volume of 4°C freezing solution for a final concentration of 1×10^7 viable cells/ml.

4. Transfer 0.6- or 1.1-ml aliquots of the cell suspension into labeled cryotubes.

5. Cool and freeze cells at a rate of −1°C/min.

   Three general methods can provide this freezing profile: (1) the vials can be placed in a styrofoam box with a wall thickness of ~15 mm, which is then placed in a −70°C freezer; (2) the vials can be placed in a special cell-preservation container supplied by Nalgene which is filled with isopropanol and placed at −70°C; (3) an expensive programmable cooler can be used that can sense the temperature of the vial and feed in liquid N_2 accordingly.

   Placing the vials directly into liquid N_2 can result in the formation of ice crystals in the cells and poor viability when thawed.

6. When vials reach −70°C (or after 2 days) transfer to liquid N_2 for long-term storage.

BCU LRS / CENTRAL UNIVERSITY LIBRARY

SUPPORT PROTOCOL 4

NUMERICAL DETERMINATION OF SPECIFIC GROWTH RATE OF CELLS

Specific growth rate of cells any given time is defined as the rate of total biomass production divided by viable cell density at that given time:

$$\mu(t) = \frac{1}{V(t) \cdot X(t)} \left(\frac{d(V \cdot X)}{dt} \right)$$

where $\mu(t)$ is the specific growth rate at time t, $V(t)$ is the volume at time t, and $X(t)$ is the cell density at time t.

Specific growth rate is a function of cell type as well as the depletion of growth-limiting nutrients in the medium of choice and/or the accumulation of growth-inhibitory waste products in the medium. Both graphical (see Support Protocol 5) and numerical methods have been used to determine the specific growth rate of a culture. The growth rate is determined numerically by the following procedure.

1. Take a 1-ml sample from the culture and count viable cells (*APPENDIX 3C*) at time point 1.
2. After 4 to 24 hr (depending on how fast cells are growing) take another 1-ml sample from the culture to count viable cell density at time point 2.
3. Calculate the specific growth rate μ of cells as:

$$\mu_{\text{time 2}} = \frac{\ln\left(\frac{\text{viable cell density at time 2}}{\text{viable cell density at time 1}} \right)}{\text{time 2} - \text{time 1}}$$

SUPPORT PROTOCOL 5

GRAPHICAL DETERMINATION OF SPECIFIC GROWTH RATE OF CELLS

When complete growth curve data are obtained, the data may be input to a spreadsheet/graphics-type program capable of curve fitting and defining a polynomial best fit. The information can be used to determine the derived parameter of specific growth rate. For definition of specific growth rate, see Support Protocol 4. The growth curve is determined graphically as follows.

Materials

Spreadsheet software with graphical output (e.g., Microsoft Excel or Lotus 123)

1. Take a 1-ml sample from the culture for viable cell count (*APPENDIX 3C*) every 4 to 24 hr, depending on how fast the cells are growing, until late log or stationary phase.
2. Plot the viable cell density versus time on an *x-y* chart using spreadsheet software capable of graphical output.
3. Curve-fit the chart to a best 3- or 4-order polynomial function.

   The logarithmic growth phase (days 0 to 5, typically) can also be fitted with a log function or linear fit on a log scale.

4. Calculate the specific cell growth rate at time = T hr as the first-order derivative of the function divided by the viable cell density at time = T hr.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

NUMERICAL DETERMINATION OF SPECIFIC PRODUCTIVITY OF CELLS PRODUCING HETEROLOGOUS PROTEIN

SUPPORT PROTOCOL 6

The specific productivity of a protein at any given time is defined as the rate of increase in the protein mass divided by total viable cell mass at that given time:

$$\text{specific productivity } (t) = \frac{1}{X(t)}\left(\frac{dP(t)}{dt}\right)$$

where $X(t)$ is the cell concentration at time t and $P(t)$ is the product concentration at time t. Specific productivity is calculated as follows.

1. Take a 1-ml sample from the culture, count viable cells, and determine the product protein concentration by ELISA at time point 1.
2. After 4 to 24 hr (depending on how fast cells are growing), take another 1-ml sample from the culture, count viable cells, and determine product protein concentration by ELISA at time point 2.
3. Calculate the specific productivity (q_p) by cells as:

$$q_p(\text{time } 1 \rightarrow \text{time } 2) = \frac{\text{protein concentration at time } 1 - \text{protein concentration at time } 2}{(\text{time } 2 - \text{time } 1) \times X_{avg}(\text{time } 1 \rightarrow \text{time } 2)}$$

where

$$X_{avg}(\text{time } 1 \rightarrow \text{time } 2) = \frac{\text{viable cell density}_{\text{time } 2} - \text{viable cell density}_{\text{time } 1}}{\ln(\text{viable cell density}_{\text{time } 2} - \text{viable cell density}_{\text{time } 1})}$$

GRAPHICAL DETERMINATION OF SPECIFIC PRODUCTIVITY OF CELLS PRODUCING HETEROLOGOUS PROTEIN

SUPPORT PROTOCOL 7

For definition of specific productivity, see Support Protocol 6.

Materials

Spreadsheet software with graphical output (e.g., Microsoft Excel or Lotus 123)

1. Sample cultures at time points 1 and 2, count viable cells, and determine protein concentrations (see Support Protocol 6, steps 1 and 2).
2. Plot the viable cell densities versus time and plot the protein concentrations versus time on *x-y* formatted charts using spreadsheet software capable of graphical output.
3. Curve-fit the charts with the best 3- or 4-order polynomial functions.
4. Calculate the specific productivity as the first-order derivative of the protein concentration curve-fit function divided by the viable cell density at any given time point.

BCU IAS / CENTRAL UNIVERSITY LIBRARY

SUPPORT PROTOCOL 8

PREPARATION OF SAMPLES FOR PRODUCT ASSAY

Samples taken from the culture need special preparation for protein assay and storage. The handling procedures are different for cultures that make intracellular product and those that make secreted product. Freezing whole-cell cultures and subsequent thawing may affect the value and consistency of the assay in some cases. If samples must be stored frozen as whole-cell cultures prior to assay, the effects of freeze/thawing should be evaluated, but this is not recommended as a consistent method. In the procedures below, the culture is centrifuged or filtered to separate the cells (which are lysed to produce a cell extract if the product is intracellular) from the supernatant (which is handled separately when the product is secreted).

Materials

Sample of cell culture (see Basic Protocols 6 or 7 or Alternate Protocol 3)
0.9% NaCl, filter-sterilized, 4°C

Refrigerated centrifuge
Ultrasonic homogenizer (Misonix)

1. Centrifuge 1 to 5 ml of sample 10 min at 300 to 350 × *g*, 4°C. Decant supernatant; retain for assay or store frozen at ≤30°C for future analysis if protein product is secreted. If protein product is intracellular, proceed with step 2 and subsequent steps.
2. Resuspend the cell pellet in 1 ml of cold 0.9% NaCl solution.
3. Centrifuge again for 10 min at 300 to 350 × *g*, 4°C.
4. Decant supernatant and resuspend pellet in 1 ml of 4°C 0.9% NaCl.
5. Keeping the sample tube in an ice bucket, place the sample tube under the ultrasonic homogenizer and immerse the microtip probe in the cell suspension. Operate the sonicator for a 10-sec cycle with continuous power-on time of 0.5 sec and continuous power-off time of 1.5 sec, with the power set at low to medium level.

   After the completion of a 10-sec cycle, load a drop of cell suspension onto a hemacytometer slide and observe the lysate under 125× magnification using phase contrast. If insufficient disruption is observed, perform further 10-sec sonication cycles until cells lysed.

6. Centrifuge the suspension of disrupted cells 10 min at 800 to 1000 × *g*, 4°C.
7. Retain supernatant for assay or store frozen at ≤30°C for future analysis.

SUPPORT PROTOCOL 9

DETERMINATION OF SHAKER FLASK GROWTH CURVE

A complete 10-day growth curve is useful for determining the expected cell yield in batch culture, for optimization of time of harvest, and for information making it possible to compare culture performance at different scales.

Additional Materials (also see Basic Protocol 6)

Thawed vial of cryopreserved cells (0.5 ml to 1 ml at 10^7 viable cells/ml) or aliquot of healthy cells in exponential growth phase (10^7 cells total in ~25 ml)

Additional reagents and equipment for determination of specific growth rate (see Support Protocols 4 and 5) and specific protein productivity of cells (see Support Protocols 6 and 7)

1. Preincubate a 250-ml shaker flask, containing sufficient medium such that the volume after adding the aliquot of cells will be 50 or 100 ml total, in a humidified 37°C, 5% CO_2 incubator. Add an aliquot of cells that will give a starting density of 0.5–1.0 × 10^5 viable cells/ml.

ECU IASI / CENTRAL UNIVERSITY LIBRARY

2. Remove a 1.0-ml sample to determine post-inoculation viable cell density (*APPENDIX 3C*) and protein product titer (in supernatant or cells). Place the flask containing the rest of the cells on a rotating platform in the incubator and incubate with agitation at 80 to 100 rpm.
3. Sample 1.0 ml from the flask daily and determine viable cell density and protein product titer.
4. Feed cells by adding glutamine to a final concentration of 2 mM and glucose to a final concentration of 2 mg/ml on days 4, 6, and 8. Check the pH on a daily basis from day 4 onwards, and correct to pH 7.2 ± 0.1 if necessary using 0.5 N NaOH.
5. Keep a tally of sample volumes removed and the glucose, glutamine, and NaOH volumes added to enable calculation of the cell density dilution that has occurred as a result of additions and sampling.
6. Determine the specific growth rate (see Support Protocols 4 and 5) and productivity (see Support Protocols 6 and 7).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

αMEM medium

Purchase Minimal Essential Medium Alpha (αMEM; Irvine Scientific, Life Technologies, Sigma, JRH Biosciences, or HyClone) without L-glutamine and supplemented with 2.2 g/liter sodium bicarbonate. For growth medium, purchase formulation containing ribonucleosides and deoxyribonucleosides; for DHFR selection medium, purchase nucleoside-free formulation. Supplement with Pluronic F-68 (BASF) to a final concentration of 0.05% (w/v). Add 10 ml of 200 mM L-glutamine stock solution (HyClone; store at –20°C) per liter of medium immediately prior to use. Supplement as required by protocol with γ-irradiated fetal bovine serum (FBS; HyClone; store at –20°C prior to addition), heat-inactivated 30 min at 56°C. For DHFR selection, use dialyzed FBS (HyClone) to ensure absence of nucleosides. Store prepared medium (without the serum) up to 1 month at 4° to 8°C.

DMEM/F12 custom-modified medium

DMEM/F12 medium (1:1 DMEM/F12; e.g., Life Technologies, JRH Biosciences, HyClone, or Irvine Scientific), without thymidine, hypoxanthine, or L-glutamine, containing the following (final concentrations):
25 mM HEPES
5 g/liter D-glucose
0.11665 g/liter $CaCl_2$ (anhydrous)
0.04884 g/liter $MgSO_4$ (anhydrous)
0.061 g/liter $MgCl_2 \cdot 6H_2O$
2.5 g/liter sodium bicarbonate
0.05% (w/v) Pluronic F-68 (BASF)
Osmolality 280 to 320 mOsm/kg, adjusted with NaCl
Store up to 1 month at 4° to 8°C
Add L-glutamine to 4 mM final concentration just prior to use
Supplement as required by protocol with γ-irradiated, dialyzed fetal bovine serum (FBS), heat-inactivated 30 min at 56°C.

This formulation (minus the L-glutamine and serum) may be prepared to order by Life Technologies, JRH Biosciences, HyClone, or Irvine Scientific.

BOSTON CENTRAL UNIVERSITY LIBRARY

Homogenization buffer

Appropriate buffer (e.g., 50 mM Tris·Cl, pH 7.5; *APPENDIX 2E*) containing:
1 mM EDTA
0.1 to 1.0% Tween 80 (omit for extraction of soluble intracellular proteins)
Store up to 2 weeks at 4° to 8°C

Resuspension buffer

50 mM Tris·Cl, pH 7.5 (*APPENDIX 2E*)
10 mM EDTA
100 µg/ml RNase A
Store up to 1 week at 4° to 8°C

COMMENTARY

Background Information

Mechanisms of expression

The level of expression of genes introduced into mammalian cells will depend on the gene copy number, the site of chromosomal integration, the transcriptional control elements, and mRNA stability. Availability of translational components—e.g., aminoacyl-tRNA, ATP, GTP, and other nutrients—is not likely to be limiting in mammalian cells growing under cell culture conditions.

Expression vectors are modular in design, with various elements such as promoter-enhancer sequences, transcription termination/poly(A) sequences, multiple cloning sites, selection marker sequences with promoters and poly(A) sequences, and bacterial elements for replication and maintenance. Constitutive expression systems are most frequently used for stable expression. These include the strong promoters such as the cytomegalovirus (CMV) promoter, the β actin promoter, the SR α promoter, and the Rous Sarcoma Virus (RSV) promoter, which are capable of high levels of transcription. Following transcription in the nucleus, the primary transcript is capped and processed to remove any introns and the poly(A) tail is added before the mRNA is transported to the cytoplasm. Since most recombinant proteins are isolated as cDNAs, they do not contain introns. The poly(A) signal is required at the 3′ end of the foreign protein gene sequence for the transport and stability of the mature transcript. Commonly used poly(A) sequences are BGH, SV40, and HSV-tk; these are found in commercially available vectors. Although many commercially available plasmids contain introns, these offer no significant advantage in tissue culture cells (Brinster et al., 1988).

Translation of the message in the cytoplasm involves scanning of the message by the 30S ribosome complex from the cap in the 5′ to 3′ direction until it reaches an AUG codon in a favorable context, which then initiates translation. Thus, alteration of the original context of translation initiation to the Kozak's consensus sequence—GCCA/GCCAUGG—in the DNA molecule, may improve expression through increased efficiency of translation initiation (Kozak, 1986). In the consensus sequence, the –3 position and the +4 position are most critical. Another essential requirement is a stop codon at the end of the foreign-gene cDNA for termination of translation. For efficient translation, the DNA sequence should be altered to incorporate preferred codons of the expression system of choice where there is great disparity in codon usage. The cDNAs should also contain the appropriate signal sequences in frame, either on the 5′ or 3′ end, depending on the targeted organelle (see Aitken, 1997).

The selection marker is the other most crucial part of the vector apart from the *cis* elements that regulate expression of the protein. The *cis* elements required in the transcription unit of the selection marker are similar to those used for the protein. When the goal is to obtain high-level expression, it is important for the selection to be stringent and for the expression of the gene of interest to be linked to the expression of the marker gene. Methods for obtaining stringent selection involve weakening the expression of the marker protein through altering the context of translation initiation (Kozak, 1986), using a weak promoter such as SV40, or decreasing the mRNA stability (Miloux and Lupker, 1994). Mutation of the protein sequence to decrease activity has been used as a means to increase the stringency of selection, for example in the neomycin phosphotransferase gene (Yenofsky et al., 1990). In

RCU IASRI CENTRAL UNIVERSITY LIBRARY

many earlier transfections, the marker gene and the protein gene were on separate plasmids. Current vectors carry both genes on the same plasmid, which provides better probability of cointegration in stable transfection. The single-vector strategy does not essentially guarantee that the marker and protein expression are correlated in cases of very low expression of the marker gene (Kaufman et al., 1985). This motivated the incorporation of internal ribosomal entry site (IRES) sequences from encephalomyocarditis (EMCV) virus (Kaufman et al., 1991) to allow linking of expression at the RNA level. Although the fusion-protein approach (*UNITS 5.1, 6.6 & 6.7*) provides the best linking of genes it is seldom applied to produce proteins for structural or biological characterization since it will pose issues such as the effect of the fusion on the structure and function of the fusion protein. Linking reduces the chance of vector rearrangement, which could result in nonexpression of protein of interest with continued expression of surrogate marker. The use of multiple elements that can be selected or screened for, such as neomycin and GFP together or neomycin and DHFR together, reduces the chance that clones with expression of two surrogate markers will end up with no production of the protein of interest.

Thus far the methods discussed assume random integration of the heterologous DNA into the genome. The random-integration approach results in a very low frequency of integration into a transcriptionally active locus. This frequency can be increased through targeted integration using retroviral flanking sequences (Wurm et al., 1996), or by utilizing DNA sequences that flank the gene of interest in high-producer cell lines (Fukushige and Sauer, 1992; Morris et al., 1997).

Selection and screening of transfected cells

Selection and screening are the two different methods that help isolate cells expressing the marker gene. The marker gene is an indirect indication that the protein of interest is also being expressed. In selection, cells that do not express the marker are killed by the drug, and in screening, the cells that express the marker are isolated through flow cytometric or other techniques. Marker genes for selection are most often drug-resistance genes or easily detectable protein markers such as green fluorescent protein (GFP). In addition, a membrane-targeted protein that may be detected at the cell surface by a fluorescent-labeled specific antibody may act as a useful marker. Examples of drug-resistance markers include hygromycin phosphotransferase, which confers resistance to hygromycin; neomycin phosphotransferase, which confers resistance to geneticin (G418); thymidine kinase, which confers resistance to aminopterin; xanthine-guanine phosphoribosyltransferase, which confers resistance to mycophenolic acid; adenosine deaminase, which confers resistance to 9-β-D-xylofuranosyl adenine; and a mutant dihydrofolate reductase, which confers resistance to high levels of methotrexate. Although several marker systems are available (Mortensen et al., 1997; Kriegler, 1990; Kaufman, 1990), the neomycin phosphotransferase system is most commonly used and is available in a number of commercially available vectors (Table 5.10.1).

Amplification provides the means to go beyond the selection stage and enables higher gene dosage to be obtained. This usually leads to increased specific production of the gene of interest. Amplifiable elements are provided by recessive markers, which may be transferred into host cells lacking the related cellular function. Common examples are genes for dihydrofolate reductase (*DHFR*), which allows the transfected cells to grow in methotrexate (MTX), and for glutamine synthetase (*GS*), which enables growth in the presence of methionine sulfoximine (MSX). It is interesting to note that these drugs inhibit activity of marker enzyme through tight stoichiometric binding, whereas most drugs used in selection are the substrate for the marker enzyme and are inactivated by it. Other less frequently used recessive markers are adenosine deaminase (*ADA*), asparagine synthetase (*AS*), and ornithine decarboxylase (*ODC*; Mortensen et al., 1997; Kaufman, 1990).

In the case of the recessive marker gene *DHFR* in CHO (*dhfr*$^-$) cells, the methotrexate concentration is increased (when cells are growing adequately) by stepwise increases up to 10μM. After each step increase in the methotrexate concentration, the cells adapt and grow through increased *dhfr* gene expression. The higher-producing clones are screened and sorted for further rounds of amplification. The *GS* recessive marker has been used in CHO cells, and high titers (>100 mg/L) of foreign proteins have been obtained after two rounds of amplification using MSX (Cockett et al., 1990). *DHFR* can serve as a selection/amplification marker in *DHFR*$^+$ cells, such as CHO-K1, through the use of strong promoters to drive its expression, or with the low MTX affinity–mutated mouse *dhfr* gene (Simonsen and

BOSTON CENTRAL UNIVERSITY LIBRARY

Levinson, 1983), or multiple selection markers (e.g., *neo*^{R}; Kaufman, 1990). In these instances, selection for stable integration of *dhfr* requires moderately high (200 nM) MTX level to overwhelm the endogeneous DHFR and therefore the amplification potential is limited.

Amplification provides a means to enhance the specific productivity of a cell, particularly where the level of expression is gene-dosage limited. Limits to the potential increased productivity exist and may be due to saturation of the translational capacity of the cells (Pendse et al., 1992) or to instability of gene copy number (Wurm, 1992). Thus, there is likely a point where the level of message is not limiting the overall expression of protein. Although high synthesis rates have been described, the overall expression rate may be limited by the secretory capacity of the cell (Cockett et al., 1990). Coexpression of a protein with higher levels of endoplasmic reticulum resident proteins (BiP, PDI, and calnexin) has been performed as a means to facilitate higher secretion rates, but there has been no general approach that guarantees higher secretion rate. Where cells are amplified to high gene copy number there is no absolute assurance that the amplicons are stable in the absence of the MTX. Following amplification, it is useful to subpassage the cells without MTX and determine the stability of production by detection of the protein of interest over several passages. Another method for evaluating the heterogeneity of gene copy number and stability of the foreign genes in the cell population is the use of fluorochrome-labeled MTX (MTX-F) and flow cytometry (Kaufman, 1978).

Although there will always be significant time investment in amplification of expression, time savings may be possible by accelerating the selection and cloning procedure by use of flow cytometric sorting of producer cells. Use of these methods requires marker that can be noninvasively detected through fluorescence-based methods. A unique reporter that satisfies these criteria is the green fluorescent protein (GFP) from jellyfish (Chalfie et al., 1994; Kahana and Silver, 1996). Cells that express this protein can easily be detected and sorted using flow cytometric techniques (Subramanian and Srienc, 1996). GFP can be substituted with membrane-targeted proteins that are also amenable to flow cytometric detection and sorting. For example, the pHOOK system, commercially available from Invitrogen (pHOOK-2 vector; Capture-Tec 2 kit) can be used (Mortensen et al., 1997; Chesnut et al., 1996). In this system, a single-chain antibody (sFv) against a hapten is expressed in addition to the transcription unit for the gene of interest. There are also two immunofluorescence tags, *c-myc* and *HA*, fused to the sFv. Antibodies against the sFv or the tags could be stained through direct immunofluorescence staining (primary antibody is conjugated with a fluorescent label, i.e., FITC or PE) or through indirect immunofluorescence staining (the primary antibody has no label but a secondary antibody that recognizes the primary is labeled). Alternatively, cells expressing the sFv can be separated using magnetic affinity cell sorting (MACS) where micron-size paramagnetic beads coated with the hapten are mixed with transfected cells and the cells to which the beads are bound are separated using a magnet. One disadvantage with the MACS is that it can only separate positive from negative but cannot differentiate between cells with various amount of surface proteins (density). This situation may eventually not be limiting, with the introduction of continuous magnetic separation devices that can fractionate on the basis of surface-marker density (Chalmers et al., 1998).

The use of surrogate markers can be completely avoided if the protein of interest can be directly quantitated and high-producer clones can be isolated. Such an assay, which measures product secreted from single cells encapsulated in agarose beads using an immobilized matrix for the capture and detection of the protein of interest, has been applied to the isolation of hybridomas with high antibody productivity (Gray et al., 1995).

Mechanisms of secretion

Secretion of protein from the cell into the medium is the most commonly used expression approach. In the case of glycoproteins, the routing of the protein through the cell is dependent on a leader sequence in front of the protein sequence for endoplasmic reticulum docking and uptake, and lack of the C-terminal endoplasmic reticulum–retention sequences. The protein will be transported from the endoplasmic reticulum (with addition of a lipid-linked oligosaccharide dolichol phosphate precursor and trimming of mannose and glucose) through to the Golgi (with trimming of mannose and addition of N-acetyl glucosamine, glucose, galactose, fucose, and sialic acid residues) and to the cell surface for secretion. In the absence of a leader sequence, the protein will remain in the cytoplasm where other motifs and chaperones may channel the protein to the nucleus, to the mitochondria, or into membranes.

It may also simply accumulate in the cytoplasm as unglycosylated protein. For more information on the various protein motifs, see Aitken (1997) and *UNIT 17.1*. Proteins that are channeled through the ER and Golgi of the cell are presented to the cell's glycosylation machinery. The compartmentalization and translocation mechanisms are briefly reviewed in *UNIT 5.9*.

Choice of cell lines

Chinese hamster ovary cells have become a widely used host for stable expression of heterologous genes. The CHO cell lines DG44 and DXB11 are *DHFR*$^-$ and commonly used to enable methotrexate selection and amplification of chromosomal integrated genes (see *UNIT 5.9*). Both these cell lines may be obtained from Dr. Lawrence Chasin of Columbia University (e-mail *lac2@columbia.edu*). Selection approaches, other than methotrexate, use CHO-K1 cells (ATCC #CCL-61).

A number of CHO cell mutants exist that enable the production of glycoforms with removal or addition of linkages or sugar types. The mutants were isolated by their ability to grow in the presence of specific toxic lectins. The resistant cells do not bind the toxic lectins on their cell surface. This is a consequence of the mutant cell line lacking a specific glycotransferase enzyme and the resulting lack of the related lectin-binding carbohydrate structure on the cell surface. A number of these mutant CHO cells have been isolated and described and can be grown in culture (Stanley and Ioffe, 1995), providing interesting potential options for tailoring the carbohydrate structures. A mutant designated as Lec3.2.8.1 can provide glycoproteins with all the N-linked carbohydrate as Man_{5-7} and the O-linked truncated to a single GalNAc (Stanley, 1989). Other approaches to in vitro modulation of the glycoprotein carbohydrate structures involve use of specific inhibitors such as tunicamycin, castanospermine, deoxynojirimycin, deoxymannojirimicin, and swainsonine, which inhibit specific steps in the endoplasmic reticulum such as the addition of the lipid-oligosaccharide dolichol phosphate precursor to asparagine, or the trimming of glucose and mannose residues (*UNIT 12.3*). If the inhibitors are toxic to cells at their functional level, then gradual adaptation of the cells to the compounds may be required.

Analysis of the detailed carbohydrate sequence and distribution of structures for purified glycoproteins is still challenging, although the advent of capillary zone electrophoresis and electrospray mass spectrometry have been useful for fractionation and analysis of glycoforms present in recombinant proteins (Parekh and Patel, 1992; Yim, 1991). Although there are no preparative-scale separation methods to resolve larger quantities of glycoforms to homogeneity, immobilized lectin columns are available that enable purification of high-mannose glycoprotein from heterogeneous mixtures (*UNIT 9.1*). Use of purified specific exoglycosidases may be useful for sequential and specific digestion of the carbohydrate structures to a desired species (Brady et al., 1994).

Choice of medium

CHO cells readily adapt to suspension growth in medium containing lower Ca^{2+} and Mg^{2+}, in the range of 0.2 to 0.6 mM respectively. Spinner MEM medium, with reduced calcium and increased phosphate, was first used for anchorage-independent growth in 1959. A commonly used medium is DMEM/F12 (Life Technologies, JRH Biosciences, or HyClone) supplemented with fetal calf serum (Life Technologies, HyClone). Following adaptation to suspension, cells may be subjected to stepwise changes in medium components—e.g., decreasing levels of serum. Adapting the cells to growth in medium containing low serum will generally make the cells grow with less clumping. Another benefit of growing in lowered serum is reduction of contaminant protein level, which makes the subsequent purification easier. Serum contains bovine transferrin and mitogenic growth factors. When the concentration of serum is <1% (v/v), addition of insulin or IGF to the medium is needed.

Mechanisms of cell growth

Cells may be grown in shaker flasks, spinners, or larger bioreactors. The choice of approach is dictated by the quantity of final purified product required (Table 5.9.3 and Table 5.9.4).

Bioreactors may be set up in glass spinner vessels fitted for pH and dO_2 control (Griffiths, 1992). Larger-scale operation requires use of stainless steel vessels, which are available from 10 to 10,000 liters. Scale-up to 100 liters is adequate for intermediate-scale production. Such reactors may be operated in batch, fed batch, or continuous mode. Batch operation is the least complicated approach and the one that is least vulnerable to contamination, since fewer manipulations are required. Highest titer levels are achievable in fed batch because of the high cell density and high specific growth rate. Perfusion reactors enable high product titer and

COLUMBIA UNIVERSITY LIBRARY

productivity, which result from the higher cell density achievable, although the lower target growth rate may decrease the specific productivity. Cell-specific productivity is usually higher in fast-growing cells because of an increase in the frequency of S-phase cells in culture, and the use of S-phase-active promoters (Gu et al., 1993). High density is obtained by operation in continuous mode with cell retention in the bioreactor. Cell-retention devices include internal or external inclined settlers, spin filters, or external microporous filtration devices. Recently, an acoustic cell settler (Sonosep) and a cell-recycling external centrifuge were developed (Centritech AB, DuPont) and have been made available for compact operation up to 40 liters.

Cell-retention devices should provide a cell retention efficiency of >75% to support a reactor steady-state cell density at a minimum specific growth rate of 0.3 per day. A target growth rate should be stipulated in continuous-mode strategies. Perfusion reactors require an initial fed-batch phase to establish high cell density. As the specific growth rate declines, the removal rate of cells is set to the target value (typically 0.25 to 0.4 per day).

Following completion of batch growth, or during continuous-mode operation of cell culture bioreactors, it is necessary to recover the product. The primary recovery steps may be designed to harvest the cells when the product is intracellular, or most commonly to harvest the conditioned medium containing the secreted product. The types of methods used are not very different from those typically used in bacterial or yeast bioprocessing. A summary of typical recovery operations used at small and large scale is given in Figure 5.10.4.

Mammalian cells are ~10 to 20 times larger in dimension than bacteria and possess a lipid bilayer cell wall, which renders the mammalian cell much weaker than the more complex cell walls of bacteria and yeast. The larger size provides for a sedimentation rate of 10 to 20 cm/min at 1 g, in the order of 100 times larger than that of bacteria; hence, low-speed centrifugation is able to separate the cells without compression and cell damage. Thus, recovery of the product from the culture may be readily accomplished at laboratory and compact bioreactor scale. Batch centrifuges capable of spinning at 2000 to 5000 × *g* can separate cells from the conditioned medium. For larger volumes (>20 liters), tangential-flow microporous membranes (0.2 μm pore size) may be used to obtain a permeate containing extracellular protein and a retentate containing the concentrated cells. It is important to minimize cell damage and product contamination and loss, which could result from exposure to shear forces or bursting bubbles. Cross-filtration devices are available for mammalian cell operations and feature open-channel design to minimize shear damage. These operate at low transmembrane gauge pressure (<5 psi) to avoid cell deformation and fouling at the membrane surface. Since most mid-scale-up to pilot-scale continuous centrifuges contain acceleration zones which can damage cells, they are rarely used in primary recovery of cells or conditioned medium. In dealing with large volumes of conditioned medium from perfusion reactors, it may be possible to allow the cells in the conditioned medium to settle overnight. The top 80% of the liquid could then be clarified by tangential flow filtration (TFF) or by depth-filtration membranes (Seitz, Cuno, FPI) and then concentrated using tangential cross-flow ultrafiltration.

If intracellular product is desired, it is necessary to disrupt the cell membrane to release the product. Typically, the first step in such a scheme would be to separate the cells from the culture medium to eliminate the serum contaminants. This is achieved by centrifugation or gravity separation of the cells overnight in a cold room, followed by decanting of the clear top liquid phase. The cells can be resuspended in a simple buffer containing a low concentration of a suitable nonionic detergent to weaken the cell membrane. Exposure of the cells to high laminar shear using a homogenizer (APV-Gaulin), or recirculation at high rates using a rotary displacement pump, will rupture the cells further and release the product. After cell disruption, the difficult step of separating the cell debris from the released product must be accomplished. For this step, high-speed centrifugation could be applied or TFF could be used at low transmembrane pressure and high recirculation rate employing screened membranes.

Throughout the recovery operations the product may be exposed to physical conditions, or degradative enzymes released by cell lysis, which may modify the protein. Typically, serine proteases are active at neutral pH and lysosomal-based proteins are active at low pH (4 to 6). Resistance to proteolysis may result from inherent structural properties of the proteins such as buried protease sites or the conditions of processing such as inclusion of protease inhibitors or speedy processing at <10°C. The presence of sialidase, as a result of cell lysis,

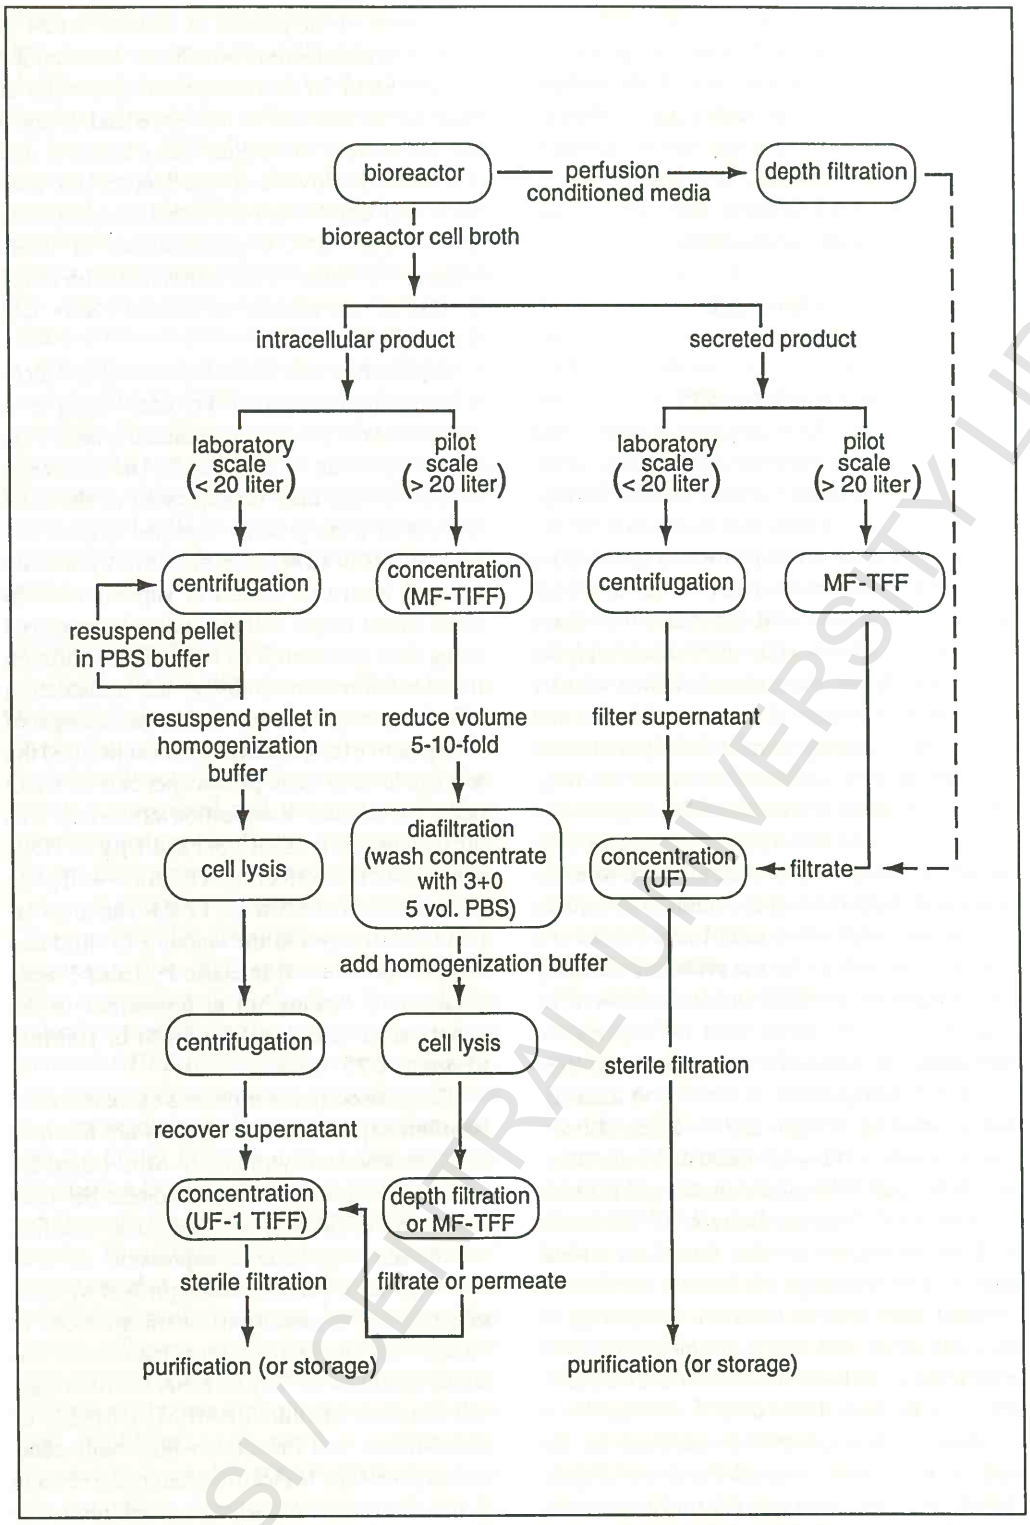

Figure 5.10.4 Cell culture product recovery flow schemes for laboratory and pilot scale processes. Options for intracellular and secreted proteins are shown. For details, see Basic Protocol 8. Abbreviations: MF, microfiltration; TFF, tangential-flow filtration; UF, ultrafiltration.

BCU IUSI / CENTRAL UNIVERSITY LIBRARY

may also modify the glycoprotein and decrease the sialic acid content. Processing quickly and keeping the product at 4° to 10°C is the basis for a recovery operation with minimal physical product damage. Where specific problems of aggregation, proteolysis, and degradation are encountered, the researcher may have to consider use of chemical inhibitors.

Critical Parameters and Troubleshooting

Expression vector construction

No molecular biology protocols have been provided for constructing an expression vector, since such information is widely available (e.g., Ausubel et al., 1998, and Sambrook et al., 1989). However, the following guidelines should be considered no matter which approach is used. Construction of the vector with most commercial vectors is done by subcloning the insert cDNA into the multiple cloning sites by restriction digestion of vector and insert and maybe blunt ending with T4 DNA polymerase or Klenow polymerase, after which the fragments are ligated with T4 DNA ligase and transformed and amplified in *E. coli*. PCR is usually employed if modifications need to be made in the cDNA such as alteration of context of translation initiation or in-frame fusion to a signal sequence or another protein. Following purification of the PCR product it should be sequenced before being used for expression. The preparation of DNA is usually straightforward, but resuspension of the *E. coli* after the initial pelleting is important for efficient lysis. Centrifugation at higher speed or longer duration will make the pellet compact and difficult to resuspend. Tapping the tube on the bench aids the suspension process. One other critical step is lysis, where going beyond the recommended time is to be avoided. The quality of plasmid DNA, and especially the presence of endotoxins, has been shown to affect the transfection efficiency. If it is determined that this is an issue, a new plasmid preparation kit for endotoxin removal is available from Qiagen. The *E. coli* host chosen for plasmid preparation should be recombination deficient (*recA1* or *recA13*) and endonuclease deficient (*endA1*) to avoid rearrangement and degradation of the plasmid sequence.

Transfection

Before embarking on the laborious and lengthy process of transfection, selection, and amplification, it is advisable to do transient expression of the protein of interest. At 24 to 48 hr post transfection (which may be extended to 72 to 96 hr for secreted proteins), the cell or supernatant fraction is harvested and assayed for the protein of interest using ELISAs and immunoblots (*UNIT 10.8*). The transfection protocol may also be initially tested using reporter genes—e.g., GFP, β-galactosidase, or luciferase—in a vector construction that is identical to that of the protein of interest (Kain and Ganguly, 1996).

Lipofection (see Basic Protocol 2) and electroporation (see Alternate Protocol 1) are popular methods of gene transfer since a broad range of cell types can be transfected. The efficiency of transfection may be expressed as the total amount of gene product obtained at peak expression (24 to 48 hr), and this can be by directly assayed from cell lysates or supernatants. In cases where single-cell expression is measured using flow cytometry, as with GFP or through immunofluorescent staining, the transfection efficiency is the product of the percentage of cells positive for gene expression multiplied the average level of gene product per cell. In CHO cells, the highest transfection efficiency was obtained when 6 µL of lipid and 1 µg of DNA were used for transfecting cells in a 6-well plate (Subramanian and Srienc, 1996). The inoculation cell density and the amounts of lipid and DNA recommended in Basic Protocol 2 were obtained by scaling up in proportion to the surface area available for growth in 100-mm dishes or T-75 flasks.

The most common problems encountered in transient-expression experiments are the lack of expression and cytotoxicity. Most often, the optimal conditions are a compromise between transfection efficiency and post-pulse viability. Troubleshooting lack of expression or low-level expression can be accomplished by optimization of the conditions of transfection. In lipofection, the optimization parameters include: lipid (24 to 72 µl); DNA (4 to 16 µg); cell density; medium (αMEM, DMEM, or Opti-MEM); and incubation time with complexes (3 to 9 hr). In electroporation, the voltage is the most critical variable. In addition, the amount of DNA can be increased to 40 µg, but this increase will usually decrease the viability later. Similarly, the volume in the cuvette can be reduced by 50% or the medium could be changed to increase the conductivity. This will also increase the cytotoxicity. Cell death is more of concern in electroporation, giving viabilities after pulsing of up to 50%. This may be acceptable and may be close to optimal in

PCU IASTRI GARH UNIVERSITY LIBRARY

many cell types. In lipofection, cytotoxicity is less of a concern; here it can be reduced by decreasing the amounts of lipid and DNA or the time of incubation with complexes. The use of linearized DNA for stable transfection is recommended with the electroporation method. Circular DNA is essential for transient expression with either method. The use of necessary positive and negative controls is a must for any expression experiment. It is recommended that sensitive reporters, such as the *E. coli* β-galactosidase or the firefly luciferase, be included in transfection experiments as positive controls. Negative controls could be included through the use of no DNA or through using the vector without any protein insert. The negative control will be used to determine background (baseline) and any nonspecificity of assay.

Selection and screening

In the amplification process, after selecting the initial clones, those clones or a subset of those that represent high producers may be individually amplified. This means no further cloning is required and the danger of losing clones by outgrowth of other clones is removed. However, much more work may result, depending on the number of clones to be taken along. The amplification of individual clones is a risky enterprise since they may not amplify well. This approach may work when there are two selection markers in the same vector such as *neo* and *DHFR* (as a fusion protein or in separate transcription units) and the initial selection may be made in nucleoside-free medium containing G418. Following this initial selection of clones a few high producers may be carried on through the amplification procedure separately. The number of clones at the end of selection that need to be analyzed and the method of analysis (serum level, suspension versus adherent, production conditions, and cell growth) are very important if the requirement is to obtain a high producer. In selection and amplification, if growth is not impeded (especially in amplification) with the drug level chosen, either drug concentration should be increased or plate cell density should be decreased. In the selection procedure, if the number of cells per well exceeds what would give rise to 1 clone per well, then multiple clones will exist in the same well, which is not effective if single clones are required. The number of cells to be plated depends on the marker expression and the drug concentration. Even if the frequency of a stable transfectant is 1 in 10^5 and the number of cells plated is 100, there is always a chance that multiple clones will get into the same well, so recloning is recommended after selection/amplification procedures so as to obtain monoclonal cultures.

Limiting dilution through visual inspection is the best method, since the usual plating of 0.3 cells per well to minimize number of wells with >1 cell according to the Poisson distribution again does not assure monoclonality. Assuming Poisson distribution of viable cells, plating at a density of 0.3 cells per well would result in 74.08% wells being empty, 22.22% containing 1 cell, and ~3.69% containing >1 cell. The cloning efficiency (number of observed growth-positive wells divided by the number of expected growth-positive wells) will likely be less than expected since not all single cells form colonies as a result of stress from evaporation (higher osmolarity) or their inability to grow as single cells. Diluting the medium can be useful if evaporation and the resulting increase in osmolarity become a problem. Low serum level may reduce cloning efficiency, and it is recommended that 10% serum be included in the medium at this stage. Even at this level of stringency, it is quite possible that cultures obtained may not be monoclonal because of the growth advantage conferred upon wells with multiple cells. Visual inspection provides the only confirmation, and should be incorporated after dilution and plating to eliminate the nonsingle wells.

Almost invariably, as cells are amplified, there is no improvement in productivity after ~1 μM MTX, either because of saturation of some component in the cellular machinery or as a result of mechanisms other than amplification of DHFR for gaining resistance to methotrexate, such as a reduced influx of the drug. Amplification usually results in a high gene copy number in a nonchromosomal location, such as double minute chromosomes, which are highly unstable and which may be lost during cell division. This can be monitored as a drop in productivity following culture of cells in MTX-free medium. Low-level amplification, at or below 1 μM, is recommended to reduce instability-related issues.

Maintaining cells in culture

It is critical for any experiment that the host cells be healthy, which is made possible by maintaining them in the exponential phase of growth in medium containing 10% FBS. It is recommended that the growth of the host be checked in 10% FBS in complete medium, that

POLLACK CENTRAL LIBRARY

the cells be split at appropriate times, and that confluent cells not be exposed to prolonged nutrient limitation. A doubling time of 24 ± 8 hr is typical for most continuous cell lines. It is also advisable to start work with a frozen vial from a cell bank, which the investigator can go back to. This is important since cells that have been in culture for fewer generations (1 to 2 months after thawing) are generally easier to transfect. Some of the host cells used require special medium additives—e.g., proline for all CHO cells, as well as hypoxanthine (or adenine and deoxyadenosine), thymidine, and glycine for DHFR$^-$ CHO cells (DG44 and DXB11).

CHO cells have a tendency to clump when grown at high cell density in serum-containing medium. Clumping may be minimized by adapting cells to growth in lower serum (≤0.5% FBS). Reduced-calcium medium such as DMEM/F12 also may produce less clumping of cells. In cultures that contain clumping cells, the only secure counting method is through use of dispase and hemacytometer/trypan blue counting (*APPENDIX 3C*).

When culturing cells, it is critical to keep the temperature at 37°C ± 0.5°C. Cells will generally not tolerate rapid increases in temperature to levels above 38.5°C and will die following such shock. Exposure to lower temperature has less drastic consequences, but should be minimized so as to prevent metabolic perturbations. Optimal pH for growth is ~7.2, but cells will grow between pH 6.8 and 7.5. The optimal pH for protein expression may differ from the optimal growth temperature, and it may be worthwhile to investigate growth of cells at pH 7.0, 7.2, and 7.4 in shaker flasks to determine if there is a useful advantage to be gained in production at varied pH. All mammalian cells require L-glutamine as an energy-providing carbon source in addition to glucose. Glutaminolysis leads to the accumulation of ammonia in the medium, while glucose consumption leads to the accumulation of lactate in the medium. Both these catabolites can reach levels that may inhibit growth of cells. Typically ammonia reaches toxic levels at ~15 to 20 mM and lactate may be inhibitory at 20 mM. In cases where high cell density is desired, it is most probable that the ammonia and lactate level may limit the culture. Glutamine may also undergo spontaneous degradation to pyrrolidonecarboxylic acid and ammonia. The rate of this degradative process increases with temperature. At 37°C, ~20% of the glutamine is converted after 2 days, whereas at 4°C, <20% loss is experienced after 65 days. At small scale, medium can be purchased without glutamine and the user can add the reagent to give a concentration of 4 to 8 mM glutamine just prior to using the medium. Clearly, glutamine stock solutions (200 mM) should be stored frozen prior to use.

Ammonia and lactate can be determined rapidly using convenient metabolite analyzers such as the Kodak biolyser. In the case of large-scale operation where larger volumes of medium are needed, the user should order and use fresh complete medium with glutamine added to 4 to 8 mM. Hyperbaric levels of oxygen, which are possible where oxygen is used to supplement sparge gas, may produce peroxide and oxygen radicals which can result in poor growth and cell death. Careful control of dissolved oxygen is recommended for large-scale reactors. In the case of shaker flasks or small spinners, air is usually sufficient to support cells up to typical levels of density.

In spinners or shaker flasks, pH control is done manually, and care should be taken to add the base slowly to a swirling liquid bulk. Use of 0.5 N NaOH for pH control is recommended to avoid local high-pH spots. In reactors, use of a 6 mm internal diameter tube with a short U-bend at its end below the surface and close to the agitator is adequate. Buffering of medium using sodium bicarbonate/CO_2 is not unproblematic, and alkaline pH excursions are common when adding base or where flasks are left outside on a bench in the absence of CO_2. Such excursions may cause injure cells or affect nutrient balances. The authors recommend use of medium containing 50 to 75 mM HEPES for shaker flasks or spinner culture where manual pH adjustment is required and 25 mM in reactors where automatic pH control is available. Bicarbonate is required in the medium and is present at ~2.5 g/liter. Preincubation of spinners and flasks is important to avoid the formation of hydroxyl ions and CO_2 from the bicarbonate. Always include 5% CO_2 in the sparge and headspace gas when operating at low cell density in bioreactors. As the cell density is higher, in particular in high-density perfusion culture, the cells produce enough CO_2; therefore supplementation of sparge gas is not required. Mammalian cells are sensitive to turbulent shear, especially as may be experienced around the liquid surface where sparge gas bubbles may be bursting. Cell death can be very significant in such cases, but addition of pluronic polyol F68 (BASF) has proven to minimize bubble–cell interaction. All medium used should contain 0.05% (w/v) of Pluronic Polyol F68. Certain batches of Pluronic may be

RCU IASTECH UNIVERSITY LIBRARY

toxic (which is related to the polyoxypropylene group) and preliminary screening prior to purchase is a secure way to avoid any serious problems.

Cell growth and productivity

The specific productivity of the cell (see Support Protocols 6 and 7) is a function of the particular protein being expressed. A shaker flask growth curve (see Support Protocol 9) and titer profile will provide information on the specific productivity during the initial exponential phase and will enable calculation of the effect of lower growth rate on specific productivity as the culture progresses through to day 10. Generally the specific productivity is highest in cells growing at their maximum specific growth rate and decreases as specific growth rate is decreased. Thus, the highest specific productivity is seen in batch reactors, and high productivity can be obtained in feed-and-bleed mode. Perfusion reactors operate at lower specific growth rates with associated lower specific productivity, but provide the benefit of high cell density and higher cellular yield in the given medium. In cases where there is evidence of proteolysis or glycosidase degradation of the product, it is advisable to operate a perfusion system with high viability. In this type of system the product residence time at 37°C and cell lysis are minimized. Further minimization of proteolysis may be obtained by addition of specific protease inhibitors such as aprotinin (for inhibition of serine proteases). Addition of sialidase inhibitors such as 2,3-dehydro-2-deoxy-*N*-acetylneuramic acid (Gramer et al., 1995) has been described. Many of the low-molecular-weight inhibitors are toxic and undesirable in production of material destined for clinical applications. In such cases, rapid processing at low temperature (<10°C) is the best option. Where proteins are exquisitely sensitive to proteolysis, it is advisable to operate with 0.5% to 1.0% FBS in the cell culture medium as a reagent to prevent proteolysis (Tiege et al., 1994), as serum contains the potent protease inhibitor α2-macroglobulin.

Many cell culture–dictated conditions may influence the microheterogeneity of the glycoprotein produced. In order to reproduce equivalent product from cell culture batches, it is important to standardize the cell culture protocol.

Spin filters are a commonplace option for cell retention in bioreactors; however, fouling of the screen with cells is usual after 2 to 3 weeks of operation. The passive settler devices are low-maintenance and predictable for cells of a given size and clumpiness. At present, settlers are custom-designed, although several approaches have been described in the literature (Batt et al., 1990; Brown et al., 1993).

Harvesting cultures

When harvesting cultures, it is important to maintain the cells intact to prevent contamination of the product in the extracellular compartment with intracellular constituents or to prevent loss of product if it is intracellular. Use of peristaltic pumps with size 16 or 24 silicone tubing or use of gravity transfer is recommended. Static laboratory centrifugation is a gentle approach and useful for clarifying relatively small volumes of culture liquid. The largest rotor capacities are ~5 liters, and the researcher can gauge the time investment needed to process the material with such an approach. It would be feasible to process up to 30 liters of culture broth in ~2.5 hr using such an approach.

Where cross-flow filtration is employed to separate cells and medium, it is important to minimize cell lysis, which could result in a decrease in yield, purity, or performance of the membrane system. Operation at cold-room temperature (4° to 12°C) is advisable as in all of the downstream recovery operations. Avoidance of average wall shear rates greater than 3000 sec^{-1}, using membrane pore sizes of 0.2 μm and minimization of pump shear rates will minimize the potential for cell damage (Maiorella et al., 1991). If small membrane systems of 1 ft^2 are used, then peristaltic pumps (Watson Marlow or Cole-Parmer) are adequate, while for larger systems the larger-gap rotary positive- displacement pumps are employed (Flowtech, Waukesha). Cross-linked cellulosic membranes are available (Sartorius Hydrosart) which are useful in minimizing surface fouling and for facilitating high protein flux.

Anticipated Results

For plasmid preparation, 1 liter of *E. coli* culture grown to an OD_{650} of 4.0 can yield up to 5 mg of high-copy-number plasmids. The DNA may be stored frozen without loss of quality.

Confluent growth on a surface corresponds to a cell-surface density of 1–1.5 × 10^5 cells/cm^2, so one T-75 flask can provide ~1 × 10^7 total viable cells and one T-175 flask can provide ~2–3 × 10^7 total viable cells, enough for the transfection process. Approximately 50% of the cells will have taken up the plasmid

vector following lipofection versus approximately 10% in electroporation. The proportion of cells that chromosomally integrate the foreign DNA is low, in the range of 0.001% to 0.01%. Of these cells, the frequency of stable high producers ~0.1% in general, but may reach 1% in cases where targeted integration methods are used. From these numbers, it is apparent that an initial total of 1×10^7 cells will give ~10 to 100 productive stable clones with perhaps 1 to 10 clones being high producers.

The specific productivity of the transfected CHO cells will be heterogeneous within the cell population. The level and range of productivity is largely a function of the protein being expressed as well as the particular culture conditions. Typical specific productivity levels are ~5 to 20 $\mu g/10^6$ cells/day, although it may be higher, with examples indicating recombinant antibody production at >100 $\mu g/10^6$ cells/day. Lower values, ~1 to 5 $\mu g/10^6$ cells/day, are typically found for recombinant viral-antigen proteins.

Amplification may increase the specific productivity 10- to 100-fold, depending on the protein and the clone selected. Examples of productivities following amplification that have been reported in the literature are provided in Table 5.10.2. Where a high producer is initially selected, the amplification process may provide little gain in productivity. Productivity may be limited by secretion rates in the case of large glycoproteins with numerous disulfides.

CHO cells adapt quickly to growth in suspension and can be adapted to growth in low (0.5%) serum in ~15 to 20 passages. High specific growth rate is usually reestablished in 3 to 5 passages following a step change in a medium concentration. Complete elimination of serum may take a further 5 to 10 passages before cells become truly serum-independent. Once cells are adapted to growth in medium such as DMEM/F12, it is possible to obtain a cell density of $2–4 \times 10^6$ per ml in batch shaker flasks or spinners. In the case of bioreactors, with precise pH and dissolved oxygen control, cell densities may reach 4×10^6 cells/ml for batch operation and as high as 10×10^6 cells/ml for bioreactors operating in perfusion mode. Product titers of 5 to 20 mg/liter are possible in batch-mode flasks, spinners, and bioreactors. Fed batch reactors may provide higher titers,

ECU IASTATE UNIVERSITY LIBRARY

since the promoters that have been recommended are generally dominant in the S phase of the CHO cell cycle and faster specific growth will result in a higher specific productivity than slower growing cells. A cell that has a specific productivity of 5 pg/cell/day at a specific growth rate of 0.3 per days is capable of providing 75 to 100 mg/day/liter culture in a perfusion reactor operating with a cell density of 15×10^6 cells/ml, a dilution rate of 1.0, and 70% overall cell retention.

The purity of the product, with a titer of 30 mg/liter, is estimated at ~5% for cells grown in bioreactors that achieve 10×10^6 cells/ml with a viability of 90%, using 1% FBS. In serum-free medium under the same conditions, the purity may be 10%. Intracellular-produced proteins rarely exceed 1% of total intracellular protein.

Recovery yield of the product from the reactor should be in the region of 75% to 90%. At large scale, the recovery yield for intracellular protein may be lower (50% to 60%) if large volumes of high-debris-containing material result in membrane fouling. Use of cellulose-based membranes and/or depth filtration may improve such low yields.

Time Considerations

Preparation of DNA and the process of transfection can be accomplished in <1 week. Following transfection, it takes 3 weeks to obtain colonies on plates. Expansion of the colonies up to the tissue culture flask stage requires 2 further weeks. Thus it will take a total of ~6 weeks to obtain stable transfected cells that grow in T-75 flasks in the presence of the selection drug. Subjecting the cells to amplification, such as an increased level of methotrexate, will take up 3 weeks to produce a pool of cells. Each further round of amplification will require 3 weeks. Based on these time lines, a cell that has been subjected to two rounds of amplification would be available 12 weeks after initiating the full process.

Following amplification, the process of single-cell cloning requires 3 weeks to obtain colonies and a further 2 weeks to scale up to the T-75 flask stage. At this point the higher-producing clones can be adapted from tissue culture flask growth to shaker flask growth in 1 week, and can be further adapted to 1% serum in a 2 weeks, 0.5% serum in 5 weeks, and 0% serum in 8 weeks. Laying down a cell bank of the adapted cells takes ~1.5 weeks.

Based on a cell-growth doubling rate of 1 to 2 days, a batch culture requires 5 to 7 days to complete, and depending on the scale would require an inoculum buildup process. For a 100-liter-scale process it may take 10 to 15 days to scale up to a suitable inoculum volume.

Recovery of product is usually performed as a batch process and should require <8 to 10 hr.

CHAPTER 6
Purification of Recombinant Proteins

INTRODUCTION

The principle aim of protein overexpression using the various systems described in Chapter 5 and elsewhere (e.g., Chapter 16 of Ausubel et al., 1997) is to obtain purified protein, and that is the subject matter of this chapter. The purification of any protein, recombinant or nonrecombinant, is critically dependent on the starting material (or source). Some natural proteins—for example, cellular receptors and growth factors—may be present in biological source material only in trace amounts. In these cases, complex purification schemes are required to obtain micro-amounts of partially or completely pure protein (Simpson and Nice, 1989, and references therein). With recombinant sources, the overproduced protein is usually (though not always) abundant, and hence the amount available is not generally a critical factor. The gene expressing the recombinant protein must of course have been previously cloned, and in fact may have been done so using oligonucleotide probes derived from the amino acid sequence data, in turn derived from the authentic protein isolated by (to use Scope's expression) "heroic efforts" (*UNIT 1.1*). What is at issue with overproduced proteins made by the various host/vector systems is their authenticity, in terms of both noncovalent (i.e., conformational—is the protein correctly folded or aggregated?) and covalent structure (i.e., is the correct disulfide bond pattern present and are post-translational modifications such as glycosylation required?).

In *UNIT 6.1*, an overview of protein purification is presented; although purification from *E. coli* is emphasized, other host systems are also referred to where appropriate. Purification of recombinant protein can be aided by the fact that the investigator knows the primary sequence of the recombinant protein and can thus estimate its isoelectric point. Furthermore, the purified protein can thus be checked against this theoretical sequence for artificial modifications arising from the expression system and purification method using some of the methods summarized in Chapter 7.

If the recombinant source contains the protein to be purified in a soluble state, then the protein can be isolated using standard methods, often involving column chromatography. In *UNIT 6.2*, the purification of interleukin 1β (IL-1β) is used to illustrate the basic approach for purifying an abundant and soluble protein expressed in *E. coli*. Using the basic fractionation and chromatographic approach described, it is often possible to purify other soluble recombinant proteins. For situations where the starting material is less abundant, albeit soluble (e.g., proteins secreted into the medium, or, in the case of *E. coli*, the periplasmic space), higher-resolution techniques such as biospecific affinity chromatography may be required. These are discussed in *UNIT 6.1* and Chapter 9. The expression of proteins genetically engineered to contain various affinity tags or carrier proteins that aid purification are reviewed in *UNIT 5.1* as well as in *UNITS 6.1, 6.5, 6.6 & 6.7* of this chapter.

IL-1β is somewhat of an ideal protein from the viewpoint of both expression and purification. The authentic protein is not post-translationally modified and although it contains two sulfhydryl groups, it contains no disulfide bonds. For this protein, the authentic and recombinant forms have the same covalent structure, as is discussed in detail in *UNIT 6.2* (Background Information).

BOND UNIVERSITY LIBRARY

In many cases high-level expression of protein in the *E. coli* host leads to the formation of highly aggregated proteins, called inclusion bodies. The determination of whether a protein is soluble or not is made using cell lysates and simple centrifugation schemes as outlined in *UNIT 6.1* (see also *UNIT 5.3*). Proteins in inclusion bodies usually have the correct primary sequences, identical to those of their native and authentic counterparts, but are aggregated and inactive due to noncovalent or conformational differences. In *UNIT 6.3*, the preparation of insoluble inclusion body protein from *E. coli* lysates by a simple washing procedure is described.

Before insoluble proteins in inclusion bodies can be purified, they must be extracted and solubilized; in this respect their purification is analogous to the extraction of intrinsic membrane proteins from membranes. The solubilization of inclusion body protein, however, requires denaturation with reagents such as concentrated solutions of urea or guanidine·HCl (see *APPENDIX 3A*), whereas the extraction of membrane proteins is normally carried out under nondenaturing conditions using nonionic or zwitterionic detergents (von Jagow et al., 1994). As the solubilized recombinant protein is denatured or unfolded, it must be folded into the correct tertiary and quaternary structures in order for the protein to acquire its functional and biological properties.

Many nonrecombinant proteins that have been isolated under native conditions can be reversibly denatured and renatured using well-established methods. A concise account of protein folding is given in *UNIT 6.4* (see also Pain, 1994) to provide some of the theoretical background required to interpret protein folding experiments.

The preparation of folded and active recombinant proteins from inclusion bodies involves the process known as "preparative protein folding." In traditional protein folding experiments, pure native proteins such as ribonuclease were used to study the reversible denaturation/renaturation process to gain information about folding pathways (Pain, 1994). These experiments are usually carried out using low protein concentrations (in the micrograms per milliliter range) to minimize nonspecific inter- and intramolecular interactions that lead to aggregation. In preparative protein folding, the aim is to obtain folded protein in as high a yield as possible using relatively high starting concentrations (in the milligrams per milliliter range) and without using very large reaction volumes. The various strategies usually used to achieve this are illustrated in *UNIT 6.5*.

In preparative protein folding, apart from the need to avoid or minimize aggregation, formation of the correct disulfide bonds is required. After extraction of the recombinant protein from inclusion bodies using a protein denaturant and reducing agent (*UNIT 6.3*), the solubilized protein is unfolded and sulfhydryl groups, if present, are reduced. To form the correctly folded protein, disulfide bond formation and protein folding must both occur, and usually in a concomitant manner.

Folding pure or partially purified protein may be advantageous, leading to higher yields of folded protein. In *UNIT 6.3*, gel filtration in the presence of guanidine·HCl is described as a simple and rapid method for partially purifying extracted and denatured proteins prior to folding. A recent example of this approach is the production of the ectodomain of HIV-1 and SIV gp41 (Wingfield et al., 1997). Other methods that can be used to purify proteins in high concentrations of urea or guanidine·HCl are discussed in *UNIT 6.1*.

Three examples of the folding and purification of insoluble proteins expressed in *E. coli* are described in *UNIT 6.5*. Bovine growth hormone (somatotropin) is extracted from inclusion bodies using guanidine·HCl; the protein is then folded and then purified by conventional chromatographic methods. Aggregation during the folding process is minimized by using a solvent additive cosolvent, in this case urea in a limiting (i.e., nonde-

BCU IAS / CENTRAL UNIVERSITY LIBRARY

naturing) concentration. Oxidation of the two disulfide bonds is enhanced by inclusion of an oxido-shuffling system based on oxidized and reduced glutathione (*UNITS 6.1 & 6.4*).

In the second example, purification of human interleukin-2 (T cell growth factor), a different approach is used. The protein is extracted from inclusion bodies using acetic acid, then fractionated by gel filtration in the same acid. The partially purified protein is folded and air-oxidized by the simple approach of dialysis against water. Because interleukin-2 contains three sulfhydryl groups, only two of which are involved in an intramolecular disulfide bond, it is possible for incorrect disulfide bonds to form during folding. An HPLC-based support protocol is included that allows rapid determination of the disulfide bonding pattern. Finally, the folded protein is purified to homogeneity using preparative reversed-phase HPLC. The acid stability of the protein is clearly an advantage and necessary for the success of the overall process.

The third example describes the purification of the catalytic domain of the immunodeficiency virus (HIV-1) integrase. This protein is essential for the HIV-1 life cycle and is therefore a potential drug target. The integrase catalytic domain is expressed as a fusion protein containing an additional 20 amino acids at the N-terminus. This "fusion domain" includes a tract of six histidine residues and is commonly called a His tag. The expression of proteins with His tags is fairly common practice, as it allows proteins to be purified by metal-chelate chromatography (MCAC) under both native and denaturing conditions (see *UNIT 5.1* for additional discussion). The HIV-1 integrase, extracted with denaturant and partially purified by gel filtration and MCAC, is folded into native protein using a slow and continuous addition of denatured protein into a renaturation solution. This approach was originally described by Ruldolph and his colleagues (see Ruldolph, 1989, and references therein) and is generally applicable for avoiding and/or minimizing aggregation during folding. The His tag is removed from the folded fusion protein using specific protease digestion (in this example, the protease used is thrombin, and methods for its handling and specific removal are also described).

A widely used method for producing fusion proteins in *E. coli* is the glutathione *S*-transferase (GST) system (*UNIT 5.1*). Analogous to His tag fusions, there is a simple affinity chromatographic method for purification of GST fusions using immobilized glutathione as an affinity matrix. The affinity purification of GST fusions is probably more specific than the metal chelate chromatography used for His tags, but it has the limitation that it cannot be performed under denaturing conditions. Fusion proteins usually contain a linker region with a specific proteolytic cleavage site, and often this site is specific for thrombin. Thus, once the GST fusion protein has been purified, the protein moiety can be readily released by proteolysis. Further purification may include one more round of affinity chromatography (to remove GST) and a gel filtration step to remove excess thrombin and other minor contaminates. Purification may be possible by performing only the gel filtration step, depending on the size of various protein products (GST is a dimer of 51 kDa and thrombin is ~36 kDa). In *UNIT 6.6* the expression and purification of GST fusion proteins is described. Protocols for protein expression using shaker cultures and purification methods of soluble GST fusion proteins are included. If the GST fusion protein is insoluble and forms inclusion bodies, the protein must be solubilized and folded into a native-like conformation prior to affinity chromatography. An extraction and folding protocol using the protein denaturant urea is described. (It should be noted that the GST moiety can be readily folded from either urea or guanidine·HCl denatured samples.) Protocols for proteolytic cleavage of the fusion protein and further purification are also described. Structural biologists may note with interest the recent paper by Kuge et al. (1997) in which the crystallization of a GST fusion protein was achieved.

BOWLING GREEN STATE UNIVERSITY LIBRARY

Another popular gene fusion system is based on the *E. coli* intracellular enzyme thioredoxin. This 12-kDa protein is very soluble, is monomeric, and has been thoroughly characterized (*UNIT 5.1*). The target protein can be positioned either N-terminal (protein-thioredoxin) or C-terminal (thioredoxin-protein) to the fusion partner. This dual orientation, also possible with Hist-tag fusions, represents a difference from GST fusions, as the GST moiety is normally only N-terminal. It is worth noting that as thioredoxin is a monomeric protein, it may be a more suitable fusion partner for oligomeric proteins than, for example, dimeric GST (Hurd and Hornby, 1996). In *UNIT 6.7* the construction and expression of thioredoxin fusion proteins are discussed. Support protocols deal with the release of the fusion proteins by mechanical lysis and osmotic stress. *E. coli*–derived thioredoxin exhibits thermal stability, and a heat treatment treatment of cell lysates at 80°C may be a useful initial purification step. This approach is described in the third support protocol. The commentary section includes a brief discussion of more specific purification methods. However, if ease of purification is of critical importance, the GST fusion system should be considered as the glutathione-based affinity method is probably more efficient than the corresponding affinity-based method used for thioredoxin.

It should be emphasized that although most of the protocols described in this chapter are applied to specific examples, they are fairly representative of the methods and approaches used in general for laboratory-scale preparation of recombinant proteins from *E. coli*. The individual characteristics of a given protein (e.g., solubility, isoelectric point, pH stability, and number of sulfhydryl residues) will dictate the conditions required for any particular purification step or folding process. Method optimization is usually empirical unless characterization of the purified protein provides useful guidelines.

BCU IAS CENTRAL UNIVERSITY LIBRARY

Overview of the Purification of Recombinant Proteins Produced in *Escherichia coli*

The initial choice of host system for the production of recombinant proteins for many investigators is *Escherichia coli*. This is due to such factors as ease of genetic manipulation, availability of optimized expression plasmids, and ease of growth. This unit presents an overview of recombinant protein purification with special emphasis on proteins expressed in *E. coli*. Practical aspects and strategies are stressed throughout, and wherever possible the discussion is cross-referenced to the example protocols described in the rest of Chapter 6.

The first section deals with information pertinent to protein purification that can be derived from translation of the cDNA sequence. This is followed by a brief discussion of some of the common problems associated with bacterial protein expression (see also *UNIT 5.1*). Planning a protein purification strategy requires that the solubility of the expression product be determined; it is also useful to establish the location of the protein in the cell—e.g., cytoplasmic or periplasmic. This unit includes flow charts that summarize approaches for establishing solubility and localization of bacterially produced proteins (see also *UNIT 5.2*).

Purification strategies for both soluble and insoluble proteins are reviewed and summarized in flow charts (see also Chapter 1). Many of the individual purification steps, especially those involving chromatography, are covered in detail in Chapters 8 and 9, and elsewhere (Janson and Rydén, 1989; Scopes, 1994). The methodologies and approaches described here are essentially suitable for laboratory-scale operations. Large-scale methodologies have been reviewed by Asenjo and Patrick (1990), Thatcher (1990a), and Walsh and Headon (1994a).

A section on glycoproteins produced in bacteria in the nonglycosylated state is included to emphasize that, although they may not be useful for in vivo studies, such proteins are well suited for structural studies. The final sections deal with protein handling, scale and aims of purification, and specialized equipment needed for recombinant protein purification and characterization.

PROTEIN SEQUENCE AND COMPOSITION ANALYSIS

Analyzing the Protein Sequence

The protein sequence translated from the DNA coding sequence is usually available, and before attempting any laboratory work it is useful to carry out a literature survey and basic computer analyses (Chapter 2). First, if the natural protein has been isolated and characterized, reviewing the protein's physicochemical properties and the purification techniques used may aid in planning a strategy for isolation from the recombinant host. For recombinant proteins that require folding from inclusion bodies (Bowden et al., 1991; Kane and Hartley, 1991; *UNIT 6.4*), information on the conformational properties, including denaturation/folding curves, can help rationalize folding scenarios.

Second, for uncharacterized proteins, analyses of related proteins with sequence similarities or known motifs may give useful clues for selecting purification steps (*UNIT 2.1*; see also the PROSITE database: Dictionary of Protein Sites and Patterns, Amos Bairoch, University of Geneva). For example, if the protein contains the well-known kringle domain, one may try lysine affinity chromatography (Cleary et al., 1989). On the other hand, if the protein contains no recognizable motifs and shows no similarity to other proteins, yet contains many cysteine residues, other strategies and precautions would be warranted as described in *UNITS 6.3-6.5*.

The amino acid sequence can be used to direct the synthesis of peptides corresponding to potential epitopes (e.g., 10 to 20 residues; *UNIT 2.2*). Polyclonal antibodies raised against the peptides may be suitable for detecting the protein of interest by immunoblotting. This approach may be especially valuable for monitoring proteins expressed at low levels—e.g., when *E. coli* secretion vectors are used. The antibodies may also be useful for immunoaffinity chromatography.

Analyzing the Amino Acid Composition

The amino acid composition (*UNIT 3.2*) of the protein will also allow calculation of some basic physicochemical parameters. First, using

Copyright © 1995 by John Wiley & Sons, Inc.

BCU LIBRARY OF CENTRAL LANCASHIRE UNIVERSITY

average pK_a values for ionizable side chains in proteins (Matthew et al., 1978), the isoelectric point (pI) can be estimated by applying the well-known Henderson-Hasselbach relationship. The calculations can be done with an electronic spreadsheet such as Lotus 123 or Excel (Atkinson et al., 1989) or with a commercially available software package (e.g., PC/Gene supplied by IntelliGenetics/Betagen). The values obtained, although only approximate, are useful for guiding the initial selection of ion-exchange resins and the pH of column buffers. When eukaryotic hosts are selected for protein expression, it should be noted that post-translational modifications such as phosphorylation and glycosylation will affect the pI.

Another parameter that can be estimated from the amino acid composition is the extinction coefficient (ε), usually at 280 nm (Wetlaufer, 1962). Although this information will be more useful when the protein has been purified, as most columns are monitored by UV absorption, proteins with an unusually low ε (no tryptophan and little or no tyrosine) may be difficult to detect during the early stages of purification.

Other physicochemical parameters that can be calculated include hydrodynamic parameters such as molecular radii and sedimentation coefficients (Laue et al., 1992). These parameters may help in interpreting results of gel-filtration and centrifugational separations.

CHARACTERISTICS OF THE HOST-VECTOR SYSTEM

Choosing an Expression System

Popular protein expression systems include *E. coli*, yeast, baculovirus-infected insect cells, and cultured mammalian cell lines (Chapter 5). If the requirement is to obtain a protein post-translationally modified via glycosylation (Chapter 12) or phosphorylation (Chapter 13), then a eukaryotic expression system must be used. Stable mammalian expression systems are the most time-consuming to establish and require the most expertise; however, they may be the only successful system for certain proteins, especially those that cannot be secreted in high enough yield, cannot be refolded from *E. coli*, or require the correct glycosylation pattern. The post-translational modifications may aid purification (e.g., lectin affinity chromatography can be used for glycoproteins; *UNIT 9.1*). On the other hand, these modifications may introduce charge heterogeneity—as is commonly observed with glycosylation (due to loss of sialic acid)—which may then complicate purification, especially with methods such as ion-exchange chromatography (*UNIT 8.2*). In this regard, purification from *E. coli* is the most straightforward, and most of the post-translational modifications observed in *E. coli* are nonspecific, such as deamidation (Wingfield et al., 1987a) and proteolytic clipping (Nagata et al., 1986). Other less common sources of protein heterogeneity arising from *E. coli* expression are (1) internal starts in translation (Dale et al., 1994), (2) partial readthroughs of the termination codon (Danley et al., 1991), and (3) translation errors (Lu et al., 1993).

The basic requirements for protein expression in *E. coli* are as follows:

1. Prepare the coding DNA (cDNA) sequence for the protein (i.e., without introns).
2. Insert the cDNA into an *E. coli* expression plasmid, thereby placing the gene under control of a promoter that is efficiently used by *E. coli* RNA polymerase (for examples of inducible promoters, see *UNITS 5.1 & 5.2*). The expression plasmid must also contain an efficient ribosome binding (translational initiation) site, a termination site (transcription terminator), and an antibiotic resistance gene (selectable marker). The plasmid and inserted gene are known as the expression vector.
3. Insert the expression vector into an appropriate *E. coli* host (transform cells).
4. Ferment and induce the transformed cells to produce the protein of interest (*UNIT 5.3*).

Considering the experience accumulated since the late 1970s, the expression of any given protein in *E. coli* is usually possible. Whether the protein will be expressed in a soluble and unmodified state, however, is unpredictable. The aforementioned elements of the expression system can be tinkered with to optimize protein production (*UNIT 5.1*).

Minimizing Proteolysis

If the protein is expressed in the cytoplasm in a soluble state, the purification can be carried out directly after cell lysis. Soluble recombinant proteins are, however, susceptible to proteolysis which can occur before or after extraction from the cell (Maurizi, 1992). Choosing protease-deficient *E. coli* host strains (Goff and Goldberg, 1985), manipulating growth conditions, especially the time of induction for inducible promoters (Allet et al., 1988), and using exogenous protease inhibitors can minimize this problem. Nevertheless, more extreme steps may be required, such as inducing the ex-

CU IAS CENTRAL UNIVERSITY OF KERALA

pressed protein to form insoluble inclusion bodies (Cheng et al., 1981; also see references cited in Kane and Hartley, 1991), using a secretion vector to locate the protein to the periplasm or medium, and changing to a eukaryotic expression system. In addition, there is a protein engineering approach, which requires knowledge of the proteolytic cleavage site(s): to stabilize the protein, one or both of the residues forming the scissile bond are changed by site-directed mutagenesis (Mildner et al., 1994).

Removing the Amino-Terminal Methionine

Another common problem with proteins expressed directly in *E. coli* is retention of the N-terminal methionine derived from the initiating *N*-formylmethionine (the formyl group is almost always removed). The N-terminal methionine is generally removed when the second amino acid is alanine, glycine, proline, serine, threonine, or valine (cleavable residues), but not when it is arginine, asparagine, aspartic acid, glutamic acid, glutamine, isoleucine, leucine, lysine, or methionine (noncleavable residues; Sherman et al., 1985). When recombinant proteins are expressed at very high levels, the N-terminal methionine can be retained regardless of the nature of the second amino acid, presumably due to saturation of the processing enzymes or depletion of required metal cofactors. Removal of cleavable N-terminal methionine can be carried out in vitro by digestion with purified methionine aminopeptidase (Miller et al., 1987) or by coexpression of the processing enzyme (Ben-Bassat et al., 1987).

The need to remove noncleavable methionines can be circumvented by incorporating an N-terminal secretion leader sequence that localizes the protein, minus the leader, to the periplasmic space (Holland et al., 1990). Other approaches utilize the incorporation of N-terminal fusions with, for example, ubiquitin, which can be cleaved in vitro or in vivo with the processing enzyme (ubiquitin hydrolase); this approach involves coexpression of the hydrolase (Miller et al., 1989). Finally, it should be noted that it is sometimes possible to resolve proteins containing N-terminal Met from those lacking it by chromatographic methods (Wingfield et al., 1987b).

Dealing with Inclusion Bodies

As previously mentioned, the expression of proteins in *E. coli* often results in the formation of inclusion bodies (*UNITS 6.3 & 6.5*). Inclusion bodies can be easily observed by phase-contrast microscopy as dense bodies, usually located at the polar extremities of the cell. The formation of inclusion bodies can occasionally protect proteins against proteolysis and can also allow accumulation of proteins normally toxic to the cell, such as human immunodeficiency virus type 1 (HIV-1) protease (Cheng et al., 1990). The formation of inclusion bodies also simplifies purification of the protein, albeit in a denatured/aggregated state (see below). The main disadvantage is that the protein must be extracted with protein denaturants and then folded into a nativelike conformation. For small (10- to 20-kDa) single-domain proteins, this is usually not problematical, although the overall recoveries may only be 5% to 20% those of similar or identical proteins expressed in a soluble state. For large (40- to 70-kDa), multiple-domain proteins, recoveries may be negligible, although there have been a number of successful cases, such as the 69-kDa tissue-plasminogen activator (Grunfeld et al., 1992).

The formation of inclusion bodies is not an intrinsic property of a particular protein and can sometimes be prevented. Approaches include the following: changing the promoter, host strain, and combinations thereof; controlling the growth conditions (especially the pH of the culture); adding nonmetabolizable sugars such as sucrose and sorbitol to the fermentation medium; and changing the temperature of induction, usually by lowering it (for reviews, see Schein, 1989; Wetzel, 1992).

The recombinant protein may be located in both the insoluble and soluble fractions of the cell (mixed-phase expression), and in these cases, better yields may be obtained by processing the soluble material (discarding the insoluble) even though it might constitute only a minor portion of the total expressed protein (Thatcher and Panayotatos, 1986; Wingfield et al., 1987c). Soluble protein purified from mixed-phase expressions should be carefully analyzed to check its authenticity (e.g., by mass spectrometry) as the solubility may have resulted from minor modifications such as deamidation or proteolysis of a few residues from either the N or C terminus (P.T.W., unpub. observ.).

The most successful approach for avoiding inclusion body formation is the use of an appropriate secretion vector. The N-terminal secretion signal directs protein to the periplasmic space (see section on Localizing Protein), and translocation across the plasma membrane results in cleavage of the secretion leader se-

BOULDER CENTRAL UNIVERSITY LIBRARY

quence. The environment of the periplasm contains enzymes that accelerate folding and the formation of disulfide bonds (Hayano et al., 1991; Missiakas et al., 1994; Zapun et al., 1995). Purification is also simplified as the protein content of the periplasmic space constitutes only 4% of the total *E. coli* protein (Beacham, 1979).

Engineering Fusion Proteins

Apart from direct expression, there are many examples of fusion protein expression. Fusion proteins consist of the protein of interest with N- or C-terminal extensions of known protein domains or short peptide sequences (*UNIT 5.1*; Uhlén et al., 1992). The fusion partner may help maintain the solubility of a protein which is normally expressed in insoluble form (LaVallie et al., 1993). The fusions may afford affinity handles for protein purification, can be useful carriers for short peptides (e.g., epitope regions) that are normally proteolytically degraded, and, as stated above, can be used to obtain authentic N-terminal sequences.

The expression of fusion proteins with affinity handles, such as those containing stretches of polyhistidine (His-tagged; see also *UNIT 6.5*), has become extremely popular due to the ease of protein purification under both nondenaturing and denaturing solvent conditions. The soluble fusion proteins often have native-like conformations and are biologically active. It cannot be assumed, however, that a tag will have no effect on the protein's function or activity. From a protein purification viewpoint, the main advantage of affinity-tagged proteins is realized when they are combined with a secretion vector (Skerra et al., 1991): in such a case the protein will be translocated to the periplasm or the medium, though often at low concentrations, and the tagged protein can be readily purified from culture medium or from osmotically shocked cells.

Table 6.1.1 briefly summarizes some of major advantages and disadvantages of the various expression scenarios using *E. coli*. If attempts to express protein in *E. coli* or to fold inclusion body protein fail, then a eukaryotic system must be considered. The decision of which system to use is often dictated by the expertise available to the laboratory. Alternatively, many companies offer custom expression services using various protein expression systems—this can be an expedient, although expensive, solution.

SOLUBILITY AND LOCATION OF THE PROTEIN

Determining Solubility

Figure 6.1.1 shows a simple centrifugation scheme that indicates how to determine the solubility of a protein expressed in *E. coli* (see also *UNIT 5.2*). The recombinant protein in the various fractions is assayed by SDS-PAGE (*UNIT 10.1*); if more sensitive methods are required, immunoblotting or biological assays may be used.

Cell breakage carried out with a French pressure cell (*UNIT 6.2*) will disrupt both the outer and inner membranes. The peptidoglycan layer, which lies underneath the outer membrane in gram-negative bacteria such as *E. coli*, will be fragmented into sheets. Low-speed centrifugation (30 min at 10,000 × *g*) separates unbroken cells, bacterial outer membrane and peptidoglycan components, and highly aggregated inclusion body proteins (pellet fraction) from soluble bacterial proteins, soluble recombinant proteins, and polymeric materials, including ribosomal protein complexes and inner membrane vesicles (supernatant fraction). High-speed centrifugation (90 min at 100,000 × *g*) of the low-speed supernatant will pellet polymers; soluble proteins, derived mainly from the cytoplasm and periplasmic space, can then be recovered from the clarified supernatant. Soluble proteins in the low-speed or high-speed supernatant are purified directly using conventional methods (*UNIT 6.2*).

It should be noted that a working definition of solubility is the presence of protein in the supernatant after centrifugation for 100 min at 100,000 × *g*. This definition applies to solvents of viscosity or density close to that of water.

Occasionally, recombinant protein will be found in both the pellet and supernatant fractions after low-speed centrifugation due to the accumulation of both soluble and inclusion body proteins. If partitioning is observed only following high-speed centrifugation, then specific self-association or nonspecific association involving *E. coli* proteins and nucleic acid may be suspected. Recombinant proteins that normally bind RNA or DNA often bind nonspecifically to bacterial nucleic acid (Sherman and Fyfe, 1990; Wingfield et al., 1990).

Inclusion body protein, which is located in the low-speed pellet fraction, can be partially purified by extracting with a mixture of detergent [usually 1% to 5% (v/v) Triton X-100] and denaturant, either urea or guanidine·HCl. The

concentration of denaturant used for pellet washing is determined empirically and should be below the concentration required for solubilization of the recombinant protein; the usual ranges are ~1 to 4 M urea and ~ 0.5 to 1.5 M guanidine·HCl. The cloudy extract will consist of complex carbohydrate from the fragmented peptidoglycan layer, lipopolysaccharide, and outer membrane proteins. The inclusion body protein in the washed pellets is then extracted with solvents that disrupt protein-protein interactions (e.g., 6 to 8 M urea or guanidine·HCl) and processed as described below.

Localizing Protein

When proteins incorporating a secretion vector are expressed in *E. coli*, advantage can be taken of the fact that the recombinant proteins will be located in the periplasmic space and/or the culture medium. Secretion

BCS LIBRARY / CENTRAL UNIVERSITY LIBRARY

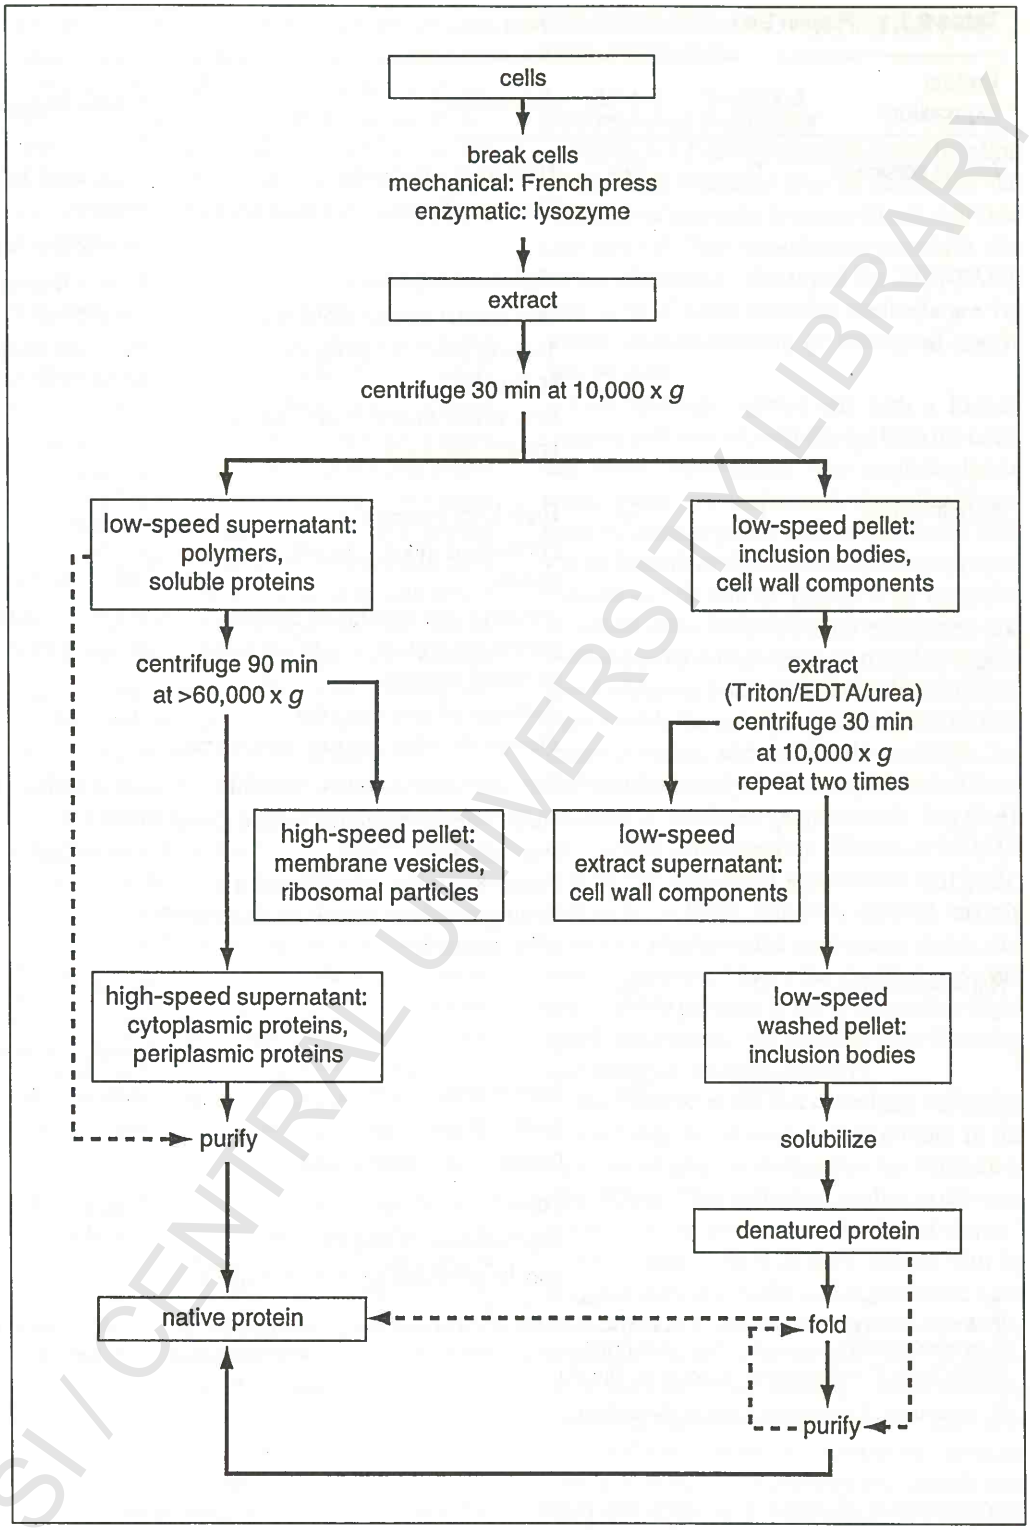

Figure 6.1.1 Differential centrifugation of *E. coli* cell lysates. Cells are broken with a French press or by lysozyme treatment. Insoluble (inclusion body) proteins, from either the cytoplasm or periplasm, are located in the low-speed pellet, which is subjected to preextraction to remove outer membrane and peptidoglycan material. Inclusion bodies are extracted from washed pellets with strong protein denaturants such as guanidine·HCl. The solubilized protein, which is denatured and reduced (free sulfhydryl residues), is either directly folded and oxidized (disulfide bonds formed) or purified before folding. Soluble proteins (from the periplasm and cytoplasm) are located in the low-speed and high-speed supernatants. The latter can be used directly for chromatography, whereas the former requires clarification by other techniques such as ammonium sulfate fractionation or membrane filtration.

ECU IASI / CENTRAL UNIVERSITY LIBRARY

into the medium is due to "leakage" from the periplasm and appears to depend on the level of accumulation and the fermentation conditions. Figure 6.1.2 summarizes approaches used to recover proteins selectively from the periplasmic space or the medium (see also *UNIT 5.2*). High-level secretion into the periplasm sometimes results in the formation of aggregates, analogous to cytoplasmic inclusion bodies (Bowden et al., 1991). Periplasmic inclusion bodies can be extracted from the low-speed pellet fraction following normal cell breakage (see Fig. 6.1.1).

Proteins in the medium can be recovered by subjecting the culture medium to centrifugation or filtration, steps that remove intact cells and any large debris. The clarified protein is usually dilute and is often concentrated prior to purification by affinity or conventional chromatography. Periplasmic proteins can be selectively released by osmotic shock (preferred method) or by selective disruption of the outer membrane and peptidoglycan layer using lysozyme.

Apart from its use in dissecting the bacterial compartments, lysozyme is often employed to prepare complete cell lysates, especially in laboratories that do not have access to a French pressure cell. Cells treated with lysozyme can be disrupted with detergents or by brief sonication (*UNIT 6.5*).

Useful microscale (<1 ml) *E. coli* cell fractionation schemes have been based on osmotic shock treatment (Yarranton and Mountain, 1992) or repeated freezing and thawing of cells (Johnson and Hecht, 1994). *UNIT 5.2* gives small-scale (1 to 25 ml) procedures for preparing samples of periplasmic extracts and extracellular media for analysis by SDS-PAGE (*UNIT 10.1*).

STRATEGIES FOR ISOLATION OF SOLUBLE PROTEINS

There are no set formulas for isolating soluble recombinant or nonrecombinant proteins; there are, however, some basic strategies and precautions that can be followed. A flow chart summarizing some of the methods commonly used for *E. coli* is shown in Figure 6.1.3 (see also Chapter 1), and a specific protocol detailing the purification of interleukin 1β (IL-1β) is presented in *UNIT 6.2*. Comments on the various stages are given in order of their application.

Determining the Isoelectric Point

The section on Analyzing the Amino Acid Composition mentions how the isoelectric point of a protein can be estimated from the pK_a values for ionizable side-chain groups. The pI can also be determined experimentally by subjecting the soluble protein extract to one-dimensional isoelectric focusing (*UNIT 10.2*) or two-dimensional titration curve analysis (Watanabe et al., 1994). If the recombinant protein is not a major protein in the extract, specific detection by immunoblotting will be required. The calculated pI can be used to set the buffer pH in subsequent ion-exchange steps.

Breaking Cells

Cells are efficiently broken by high-pressure homogenization using a continuous-fill French pressure cell, which is suitable for processing volumes of 40 to 250 ml (reviewed by Hopkins, 1991; see *UNIT 6.2*). For volumes exceeding 500 ml, the Manton-Gaulin-APV homogenizer (APV Gaulin) should be used. Sonication is also useful for breaking cells but is best suited for volumes below 100 ml. Alternatively, the outer cell wall can be enzymatically digested with lysozyme (200 μg/ml) and the cells broken by detergents, sonication, or both (Kaback, 1971; Burgess and Jendrisak, 1975; *UNIT 6.5*). Proteins that are secreted into the periplasmic space can be selectively released by hypotonic (osmotic) shock (Heppel, 1967).

The viscosity of the cell lysate may be high due to released nucleic acid. Before centrifugation, the viscosity must be reduced either by sonicating or by adding DNase (25 to 50 μg/ml plus 5 to 10 mM Mg^{2+}) and RNase (50 μg/ml; no Mg^{2+} requirement). A standard protease inhibitor mixture should be included in the buffer—containing, for example, 2 to 5 mM EDTA, 0.5 to 1.0 mM phenylmethylsulfonyl fluoride (PMSF) or 5 mM benzamidine, and 1 μM pepstatin A. The serine protease inhibitor 4-(2-aminoethyl)-benzenesulfonyl fluoride hydrochloride (AEBSF) is a water-soluble substitute for PMSF with a much longer half-life in aqueous solution and is used at ~50 μM. (Boehringer Mannheim publishes a useful brochure entitled "Protease Inhibitors" that lists properties and handling conditions for most commercially available reagents). The addition of α_2-macroglobulin (1 μg/mg recombinant protein) before the final purification step(s) can protect protease-sensitive proteins (Ultsch et al., 1991). The crude extracts should be kept cold and the recombinant protein taken rapidly to a stage of the purification process where it is stable against contaminating proteases (e.g., as an ammonium sulfate precipitate).

Figure 6.1.2 Localization of secreted and periplasmic proteins in *E. coli.* Periplasmic protein produced via a secretion vector can leak into the medium and be recovered by centrifugation (supernatant, S_1) or filtration. Washing cells with an isotonic solution such as lightly buffered 0.15 M NaCl or 0.25 M sucrose can also release protein (S_2). The compartmentalized periplasmic proteins are released by isotonic shock treatment by directly suspending normal cell paste or plasmolyzed cell paste into hypotonic medium. Plasmolyzed cell paste is derived by suspending cells in hypertonic medium and then pelleting. (In hypertonic medium the cell contracts, separating the inner membrane from the cell wall, and is said to be osmotically sensitized.) The hypertonic wash often releases protein (P_1). The supernatant from shocked cells (P_2) will contain constitutive *E. coli* proteins and the recombinant product. Osmotically sensitized cells can also be treated with lysozyme to fragment the outer membrane, thus releasing periplasmic proteins (P_3). The pellet from the lysozyme treatment contains spheroplasts (cells with fragmented outer membranes), which are easily disrupted by detergents, sonication, or hypotonic shock to release cytoplasmic proteins.

ECU IAS CENTRAL UNIVERSITY LIBRARY

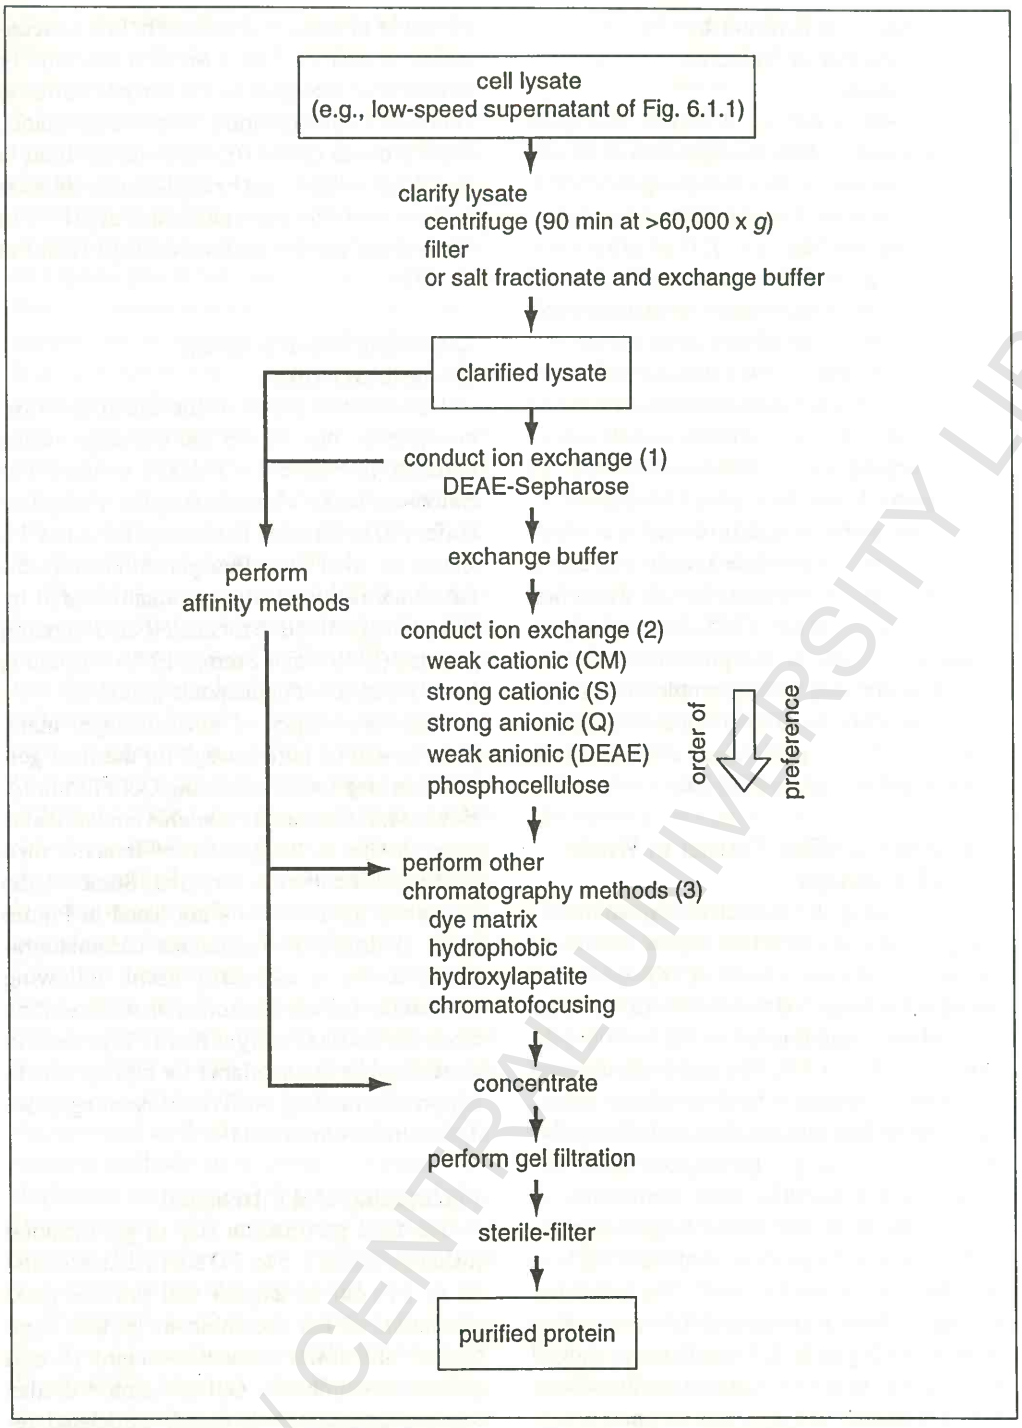

Figure 6.1.3 Purification of soluble proteins from *E. coli* lysates. Abbreviations for ion-exchange resins are as follows: CM, carboxymethyl; DEAE, diethylaminoethyl; Q, quaternary ammonium; S, methyl sulfonate. The order of preference for the stages of ion-exchange (2) and other methods (3) is based on the author's opinion and does not necessarily represent a consensus view. On the other hand, the use of a DEAE-based matrix at an early stage (1) is common practice. Affinity methods (see text and Chapter 9) can be performed at any stage following clarification of the lysate.

BCU IAŞI / CENTRAL UNIVERSITY LIBRARY

Clarifying Cell Extract by Centrifugation or Selective Precipitation

The lysate is subjected first to low-speed centrifugation to remove unbroken cells and large cellular debris, then to high-speed centrifugation to remove ribosomal material and other particulates (see Fig. 6.1.1). If an ultracentrifuge is unavailable, the extract can be clarified by the following techniques: ammonium sulfate or polyethylene glycol fractionation (reviewed by Scopes, 1994), phase partitioning (reviewed by Walter and Johansson, 1986), and membrane filtration (Walsh and Headon, 1994a; useful guides on filtration methodology are available from Millipore and Amicon).

Proteins that bind tightly to nucleic acid can be selectively precipitated with polyethyleneimine and resolubilized by salt extraction (Burgess and Jendrisak, 1975). In practice, particular properties of the protein can be exploited at this stage; for example, the protein of interest may be soluble under conditions where most *E. coli* proteins are insoluble, such as acidic pH or high temperature.

Applying Clarified Extract to Weak Anion Exchanger

Fractionating the extract with an anion-exchange resin is a useful first step as it removes host *E. coli* proteins, many of which have pI values in the range 5.0 to 7.0 and will thus bind to a column equilibrated in 50 to 100 mM Tris·Cl, pH 7.5 to 8.0. The positively charged matrix will also tightly bind nonproteinaceous materials such as nucleic acids and other polyanionic species (e.g., lipopolysaccharide derived from the bacterial outer membrane). A useful cleanup of the protein will take place whether or not the protein of interest binds to the column (see *UNITS 6.2 & 6.5*). The following column sizes are recommended for processing extracts: for 5 g cells, 2.5-cm diameter packed to a height of 10 to 15 cm; for 50 g cells, 5.0-cm diameter packed to a height of 20 cm.

Preparing for Repeat Ion-Exchange Step

Before repeating ion exchange, the solvent pH and ionic strength usually need adjustment. This can be carried out by dialysis (*UNIT 6.2*) or by gel filtration on a desalting column using, for example, Sephadex G-25 or G-50 (*UNIT 8.3*). In preparation for cation-exchange chromatography, dialysis against slightly acidic buffers (pH 5.0 to 6.0) will result in the helpful precipitation of some *E. coli* proteins. It may also be advisable to include a relatively low concentration of urea (0.5 to 2 M) or a nonionic or zwitterionic detergent in the dialysis buffer to minimize coprecipitation with contaminants. Basic proteins (pI >9.0), which do not bind to the DEAE column, can be applied after dilution to a cation exchanger equilibrated at pH 7.0 to 7.5 without careful buffer exchange (Allet et al., 1988).

Repeating Ion-Exchange Chromatography

For a second round of ion-exchange chromatography, one of the ion-exchange resins indicated in Figure 6.1.3 should be used. For cation-exchange chromatography, phosphate buffer (10 to 50 mM) between pH 5.0 and 7.5 should be tried first. Phosphocellulose (a bifunctional cation exchanger manufactured by Whatman) is effective for nucleic acid–binding proteins (Kelley and Stump, 1979). Protein is usually eluted with phosphate gradients.

After two stages of ion exchange, many proteins will be pure enough for the final gel-filtration step (see Performing Gel Filtration). However, if the sample contains contaminants close in size to the protein of interest, then further purification is required. Some of the frequently used methods are listed in Figure 6.1.3. Hydrophobic-interaction chromatography (*UNIT 8.4*) is especially useful following ammonium sulfate fractionation or salt elution from an ion-exchange resin. Dye-matrix screening kits are available for rapidly checking protein binding on five different agarose-dye matrices (Amicon).

Performing Gel Filtration

The final purification step of gel filtration (using a column 1.5 to 5.0 cm in diameter and 60 to 100 cm in length) will provide good separation of the recombinant protein from higher- and lower-molecular-weight *E. coli* protein contaminants. Gel filtration will also separate aggregated or highly associated recombinant protein from the physically stable form of the protein (e.g., monomer or dimer). Finally, it will be possible to exchange the buffer. The protein solution is usually concentrated before being applied to the column. After chromatography, the protein will be diluted 3- to 5-fold (or more) and may therefore require repeat concentration.

Other Methods

In addition to the generalized approach described, affinity methods can be applied at any

ECU IASL CENTRAL UNIVERSITY LIBRARY

stage following clarification of the extract. Biospecific affinity can be exploited with immobilized natural ligands such as antibodies, substrates, and receptor ligands. Affinity chromatography, which selects for particular classes of proteins, is carried out with immobilized lectins (for glycoproteins), dyes (for nucleotide-binding proteins) and nucleic acid or heparin (for RNA- and DNA-binding proteins). Commercially available antibodies against post-translationally modified residues (e.g., phosphotyrosine) are also useful. The application of affinity tags or fusions has been previously mentioned. Affinity methods are most useful when high degrees of purification are required—e.g., for proteins secreted into the medium, for small-scale isolations, or for rapid purification requirements.

The most commonly used affinity method is immunoaffinity chromatography. The ideal reagent is a monoclonal antibody that has been specifically selected to have a moderate-to-low affinity for the ligand in question, thus allowing elution under nondenaturing conditions. Antibodies raised against peptides often have lower affinities for the native protein than antibodies raised against the intact protein. Elution from peptide-antibody immunoaffinity columns can be achieved using the competing immunizing peptide (reviewed by Sutcliffe et al., 1983). Directed immobilization of the antibody, where only the Fc domain is bound to the column matrix and the antigen binding site (Fab domain) is thus oriented away from the matrix, results in higher binding efficiencies. An oriented antibody matrix can be made by binding antibody to immobilized protein A–Sepharose (or protein G–Sepharose) and fixing it in position with a covalent cross-linking reagent (Schneider et al., 1982; commercial kits can be obtained from Pierce).

Compilations of standard chromatographic fractionation media are available (Table 8.2.2; Patel, 1993). However, the best source of information is often the literature from the various manufacturers.

STRATEGIES FOR ISOLATION OF INSOLUBLE PROTEINS

Recombinant proteins expressed in *E. coli* that are located in the low-speed pellet fraction (see Fig. 6.1.1) following cell lysis are highly aggregated (i.e., inclusion bodies). Inclusion bodies are normally derived from protein aggregation in the cytoplasm, or in the periplasm if a secretion vector was used. As mentioned above, protein can also be located in either the low- or high-speed pellet fractions because of interaction with bacterial nucleic acids. Furthermore, if the protein is known to undergo polymerization in vitro (e.g., viral nucleocapsid subunits), expression in *E. coli* can also be expected to lead to polymerization in vivo to varying degrees, and such proteins will be partitioned in both the supernatant and pellet fractions (Wingfield et al., 1995). There are also examples of membrane proteins which, when expressed in *E. coli*, associate with the inner cytoplasmic membrane and can be extracted with nondenaturing detergents (Bibi and Béjà, 1994, and references cited therein).

When insolubility is due to interactions involving folded protein as described above, extraction under nondenaturing conditions should be attempted, for example, using salt (1 M NaCl) and nondenaturing detergents (10 mM CHAPS or 2% Triton X-100). Insolubility due to classic inclusion body formation requires extraction with denaturing solvents, and the remainder of this section deals with this subject. The flow chart in Figure 6.1.4 illustrates some of the approaches possible for processing protein extracted from inclusion bodies.

Breaking Cells

Cells can be broken by mechanical means (*UNIT 6.2*), enzymatically with lysozyme (*UNIT 6.5*), or by a combination of methods (*UNIT 6.5*). It is advantageous to break cells as completely as possible, as any unbroken cells will be located in the low-speed pellet fraction from which the recombinant protein will be extracted.

Preparing Washed Pellets

The object of the initial low-speed centrifugation is to extract as many *E. coli* contaminants as possible without solubilizing the recombinant protein. This is usually carried out as described in the section on Determining Solubility (see also Fig. 6.1.1).

When a fixed-angle rotor is used, pellets from the low-speed centrifugation consist of at least two light-colored layers and a darker, hard-packed pellet at the bottom of the tube (Fig. 6.1.5). The hard-packed material is probably a small amount of unbroken cells. The next layer is inclusion body protein, and the top layer (least dense and lightest in color) is outer membrane and peptidoglycan fragments. Analysis of the top layer by SDS-PAGE (after heating proteins in SDS sample buffer at >80°C) will reveal two strong bands at ~35 and 38 kDa

BOSTON UNIVERSITY CENTRAL LIBRARY

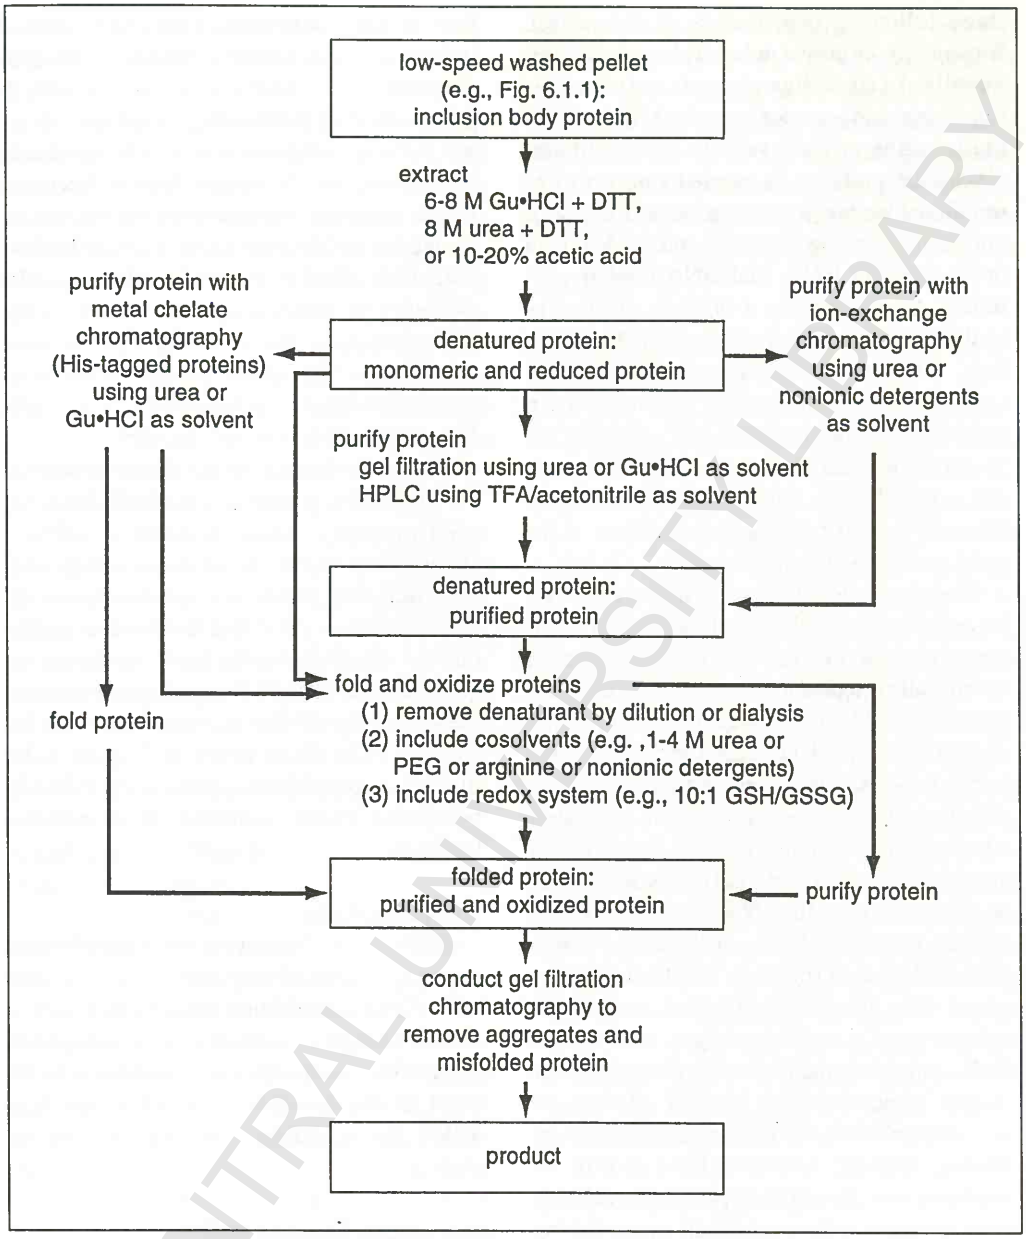

Figure 6.1.4 Folding and purification of inclusion body proteins from *E. coli*. The protein is extracted with protein denaturants such as guanidine·HCl (Gu·HCl), urea, or an organic acid. The reductant dithiothreitol (DTT) is included to prevent artificial disulfide bond formation (especially intermolecular bonds). The denatured protein can be purified by various methods and then folded, or it can be directly folded. Typically, some purification (e.g., gel filtration in Gu·HCl) prior to folding is recommended as it often results in higher folding yields. Protein folding and oxidation are carried out concurrently. Disulfide bond formation is catalyzed by low-molecular-weight thiol/disulfide pairs such as reduced (GSH) and oxidized (GSSG) glutathione. GSH/GSSG ratios of 5:1 to 10:1 are normally used, which are similar to those found in vivo in the endoplasmic reticulum (Hwang et al., 1992). A cosolvent is included to maintain solubility during folding. Folded protein is purified if necessary (purification is usually needed if the protein is directly folded). Gel filtration is a useful final step for removing aggregated and or misfolded protein.

representing OmpA and the matrix proteins OmpC and OmpF, respectively, from the outer membrane (DiRienzo et al., 1978; see also Fig. 6.3.1). The outer membrane/peptidoglycan layer can be partially removed by resuspending and centrifuging at reduced speed (or time) or by diluting the suspension. Alternately, the cells can be pretreated with lysozyme prior to the French press cell breakage as described in *UNIT 6.5*. The lysozyme treatment reduces the size of the loosely pelleted outer membrane/peptidoglycan material so it locates pre-

ECU IASI CENTRAL UNIVERSITY LIBRARY

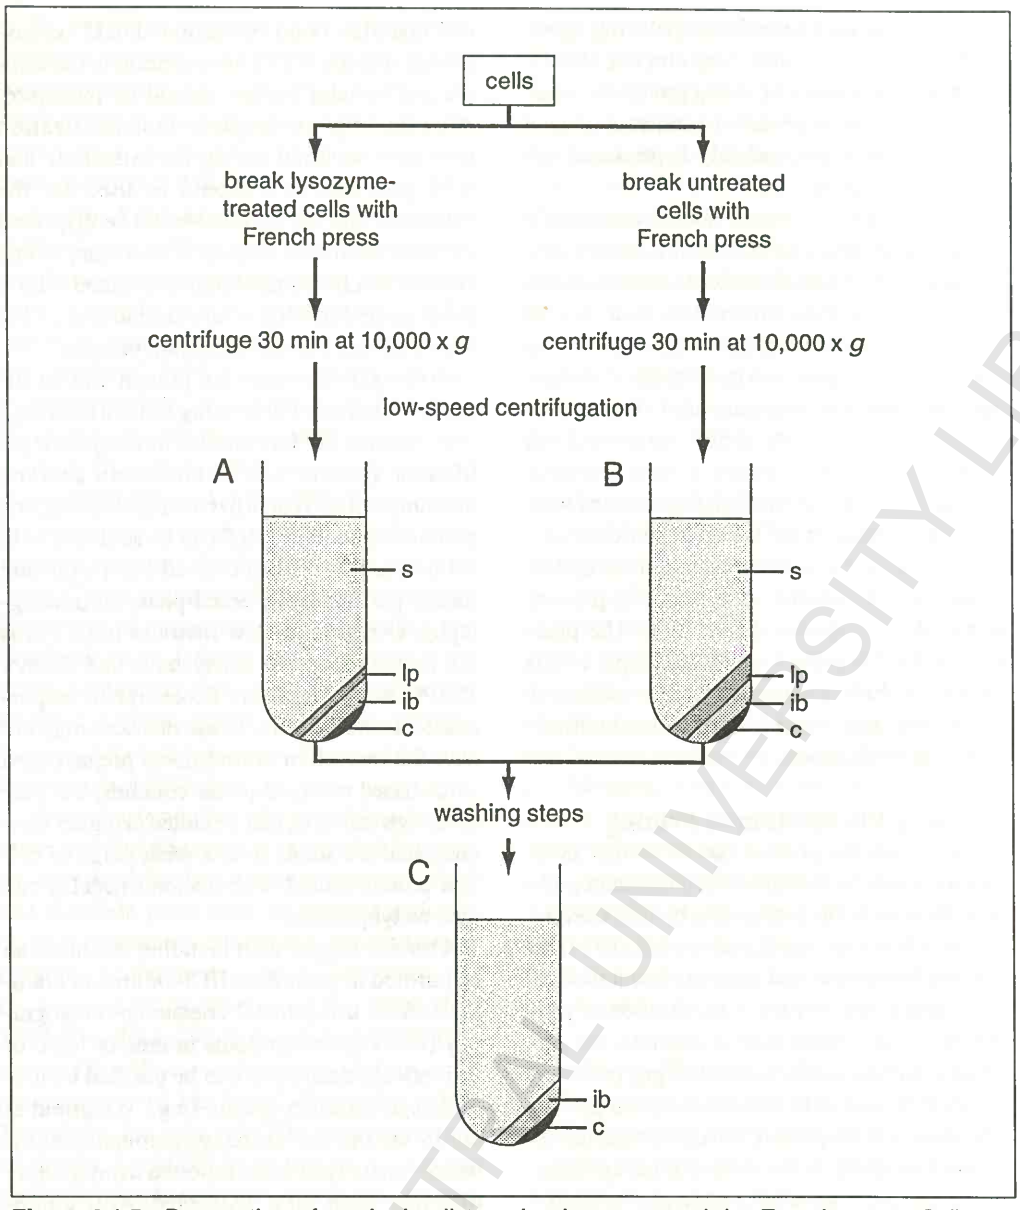

Figure 6.1.5 Preparation of washed pellets using lysozyme and the French press. Cells are broken with the French press with or without prior treatment with lysozyme. After low-speed centrifugation using a fixed-angle rotor, the contents of the centrifuge tubes have the characteristics shown. The contents of tubes A and B are labeled: s, supernatant; lp, loose pellet; ib, inclusion body protein; and c, unbroken cells and large cellular debris. The loose pellet material is derived from the outer cell wall and outer membrane (see text for further details). After washing the insoluble material (*UNIT 6.3*), the pellet should consist mainly of the inclusion body layer (tube C), and the supernatant should be fairly clear.

dominately in the low-speed supernatant (Fig. 6.1.5). The recombinant protein in a well-prepared washed pellet will be >60% pure when analyzed by SDS-PAGE (*UNIT 6.3*).

Extracting Protein

The washed pellets are extracted with high concentrations of protein denaturants such as 6 to 8 M guanidine·HCl or urea. It should be noted that some proteins are resistant to denaturation with high concentrations of these reagents, especially urea. Solubilization with 10% to 20% acetic acid has also been useful (*UNIT 6.5*); other denaturants for extracting inclusion bodies are described elsewhere (*UNIT 6.3*; Marston and Hartley, 1990). For background information on the suggested mode of action of protein denaturants, readers should consult the reviews of Tanford (1968) and Creighton (1993). If the protein contains cysteine resi-

BOU TESI CENTRAL UNIVERSITY LIBRARY

dues, it is essential to include a reducing agent, preferably 5 to 10 mM dithiothreitol (DTT). Even in the presence of strong protein denaturants, it may be necessary to sonicate or heat samples briefly to completely disperse and solubilize the protein.

The extraction process should completely unfold the protein and convert it to monomers. If a native protein can be unfolded, for example, with 4 M urea, the same protein in an *E. coli* inclusion body will almost certainly not be completely extracted in a monomeric, unfolded state with that same concentration of urea. The initial extraction trials should be carried out with guanidine·HCl, which is more effective than urea. Most proteins will be extracted with 6 to 8 M guanidine·HCl. There should be adequate reductant present to maintain sulfhydryl groups in the reduced state, and thus prevent artificial disulfide bond formation. The presence of EDTA and a slightly acidic pH of 6.0 to 6.5 will help minimize cysteine oxidation. The extract may require clarification by filtration or centrifugation.

Choosing Purification or Folding

The extracted protein can be further purified, or it can be directly folded and then purified. Protein folding may (Darby and Creighton, 1990) or may not (London et al., 1974) be affected by protein and nonproteinaceous contaminants in the extract. If purification of protein in the denatured state is possible, use purified material to develop a folding protocol. Apply the protocol to directly extracted protein and observe if the presence of contaminants has an adverse effect on the yield of folded protein. If not, directly extracted protein can be used.

Finally, there may be specific reasons for purifying proteins in the denatured state. For example, some proteolytic enzymes, such as HIV-1 protease, self-digest (undergo autoproteolysis) in the uninhibited state (Mildner et al., 1994, and references cited therein) but can be purified intact in the denatured (inactive) state, then refolded when required. It should be noted that, in general, unfolded proteins are more susceptible to chemical and proteolytic modifications.

Purifying Denatured Protein

If the protein is extracted with guanidine·HCl, gel filtration is a useful purification method; often protein >80% pure can be obtained (*UNIT 6.3*). The order of elution from the column should be directly proportional to the apparent molecular weight. If not, then artificial disulfide bond formation should be suspected, and the DTT concentration in the sample and column buffers should be increased. Alternatively, incomplete monomerization may have occurred during the extraction, and 8 M guanidine·HCl should be used for the extraction and the protein should be dispersed by sonication and heated if necessary). The column can be equilibrated and eluted with a lower guanidine·HCl concentration (e.g., 4 M) than that used for the extraction process.

After gel filtration, the protein can be directly folded (see Performing Protein Folding), or denaturant can be removed by dialysis or gel filtration against 1% to 5% (v/v) acetic acid and the sample then lyophilized. Alternatively, the protein in guanidine·HCl can be acidified with trifluoroacetic acid [TFA; ≤0.1% (v/v)] and further purified by reversed-phase chromatography. Useful high-flow matrices (e.g., Poros R2 from PerSeptive Biosystems and Source 15RPC from Pharmacia Biotech) can be purchased as bulk media. These matrices may not have the resolution of traditional prepackaged silica-based reversed-phase columns, but they have high capacity, can be eluted at higher flow rates, and are stable over a wide range of pH. The protein eluted with acetonitrile/TFA can then be lyophilized.

Proteins tagged with histidine residues can be purified in guanidine·HCl- or urea-containing buffers using metal chelate chromatography (*UNIT 6.5*), and proteins in urea or ionic or zwitterionic detergents can be purified by ion-exchange chromatography (e.g., Wingfield et al., 1990). For ion-exchange chromatography, better results have been reported using protein that has been first extracted with guanidine·HCl, then exchanged into urea (Shire et al., 1984).

If urea is used either for extraction or for maintaining solubility during refolding, a cyanate scavenger such as a glycine- or Tris-based buffer should be included to prevent carbamylation of the protein (Stark et al., 1960). For critical work, urea can be deionized with a mixed bed ion-exchange resin (see Protein Folding Reagents, *APPENDIX 3A*).

Performing Protein Folding

Protocols for folding proteins basically involve controlled removal of the denaturant under conditions that minimize aggregation and allow correct formation of disulfide bonds. For overviews of the practical aspects of protein folding, see *UNIT 6.4*, Jaenicke and Rudolph (1989), Thatcher (1990b), and Wetzel (1992).

ECU IASTE LIBRARY

To minimize nonproductive aggregation, folding is normally carried out at low protein concentrations (e.g., 0.01 to 0.10 mg/ml); for small, single-domain proteins, higher concentrations (e.g., 0.1 to 1.0 mg/ml) can often be used. Dilution and dialysis are the most common methods for removing the denaturant. Solubility during folding can be maintained with cosolvents such as nondenaturing concentrations of urea (1 to 4 M; London et al., 1974; *UNIT 6.5*) or guanidine·HCl (0.1 to 1.5 M; Orsini and Goldberg, 1978), arginine (Jaenicke and Rudolph, 1989), nonionic detergents and lipids (Zardeneta and Horowitz, 1994), cationic detergents (Puri et al., 1992), and polyethylene glycol (PEG; Cleland et al., 1992). Presumably, the cosolvents minimize intermolecular associations between the hydrophobic and thus "sticky" folding intermediates; for a theoretical discussion of aggregation versus folding, see Goldberg et al. (1991) and Kiefhaber et al. (1991). Additives such as ammonium sulfate, glycerol, sucrose, enzyme substrates or inhibitors, and ligands have also been used to enhance protein folding.

Oxidative formation of disulfide bonds (one of the rate-limiting steps in protein folding) can be catalyzed by low-molecular-weight thiol and disulfide pairs such as reduced and oxidized glutathione (GSH/GSSG). Redox buffers facilitate oxidation through thiol/disulfide exchange reactions (reviewed by Wetlaufer, 1984; Creighton, 1984). Normally GSH/GSSG ratios of 5 to 10 are used with a total glutathione concentration of 1 to 5 mM (Wetlaufer, 1984). To reduce the rate of GSH loss due to air oxidation, 1 mM EDTA should be included in the buffer (Wetlaufer et al., 1987). The optimal concentrations and ratios of reagents are established in an empirical manner. Folding and oxidation are normally carried out concurrently.

For examples of preparative protein folding, see *UNIT 6.5*. The refolding of Fab fragments expressed in *E. coli* (Buchner and Rudolph, 1992) is illustrative of the systematic and empirical approach used to optimize folding conditions. Other examples of interest are described by Kohno et al. (1990) and Grunfeld et al. (1992).

The in vivo folding and assembly of proteins are assisted by accessory enzymes such as protein disulfide isomerase, which catalyzes disulfide bond formation; peptidyl prolyl *cis-trans* isomerase, which catalyzes the rate-limiting rotation of X-Pro bonds during protein folding; and various molecular chaperones which prevent aggregation of folding intermediates (*UNIT 6.4*; reviewed by Jaenicke, 1993; Ellis, 1994). Amrein et al. (1995) produced an *E. coli* expression system containing two plasmids, one for overproduction of the bacterial chaperones GroEL and GroES and the other for expression of the recombinant protein, a tyrosine kinase. Coexpression of the chaperones and the kinase resulted in increased solubility of the latter (compared to when expressed alone). This approach may have general applicability for producing soluble (or partially soluble) forms of proteins that are otherwise produced in an insoluble state.

Purifying Folded Protein

Once the protein has been folded, any of the purification methods discussed in Chapters 8 and 9 can be used. The number of purification steps required should be fewer than those for a protein expressed in a soluble state because of the purification factor obtained by preparation of washed inclusion bodies (*UNIT 6.3*). One of the purification methods that should be included is gel filtration, which may be the only one required. A correctly selected matrix should remove any remaining *E. coli* proteins and separate aggregated and misfolded protein from the native folded protein. Misfolded protein may be expected to have a larger molecular radius (higher apparent mass) than the corresponding native protein.

Monitoring Protein Folding

The restoration of function (e.g., enzymatic or biological activity) is perhaps the best criterion for detecting successful folding. However, it is not always practical to use activity measurements to monitor folding. It is also worth mentioning that an unfolded protein may become activated following the dilution required for many activity measurements. Conversely, native proteins can be denatured or inactivated during prolonged incubation at 37°C or by adsorption to microtiter plates. The use of antibodies to monitor protein folding is briefly reviewed by Goldberg (1991), and a concise review of common spectroscopic methods, such as circular dichroism and fluorescence, is provided by Schmid (1989).

BACTERIAL EXPRESSION OF PROTEINS NORMALLY GLYCOSYLATED

Because *E. coli* lacks glycosylation machinery, expression of glycoproteins in *E. coli* systems results in the synthesis of nonglyco-

BOSTON UNIVERSITY MEDICAL CENTRAL LIBRARY

sylated variants. Glycoproteins expressed directly in *E. coli* are often, but not always, insoluble. In vitro folding studies with glycosylated and nonglycosylated forms of proteins indicate that the carbohydrate can stabilize folding intermediates, and thus enhance folding, while not necessarily affecting the stability of the native state (Kern et al., 1993, and references cited therein). In eukaryotic cells, interference with protein glycosylation can lead to the formation of misfolded, aggregated, and degraded protein. This indicates that in vivo glycosylation (N-linked) may also prevent the aggregation of folding intermediates (reviewed by Helenius, 1994).

Despite potential pitfalls, many nonglycosylated protein variants have been successfully folded from *E. coli* inclusion bodies. Examples include cytokines of biomedical importance such as granulocyte/macrophage colony-stimulating factor (GM-CSF; Diederichs et al., 1991) and interleukin 5 (IL-5; Milburn et al., 1993). Inclusion body formation was avoided in some studies by using secretion vectors; examples include GM-CSF (Walter et al., 1992) and the extracellular domain of the human growth hormone receptor (deVos et al., 1992). The aforementioned proteins have been crystallized and their structures determined by X-ray crystallography, supporting the view that the structural integrity and conformation of the proteins were not affected by the lack of glycosylation and the respective preparative histories.

If a glycoprotein of interest is available from a eukaryotic recombinant expression system or if the natural protein is available, then before investing time with *E. coli* expression it may be worthwhile to determine whether the protein can be denatured and refolded in vitro. Pilot experiments can be carried out on intact protein and on protein enzymatically deglycosylated with glycosidases and, if disulfides are present, with and without reduction. Of course, if the protein can be secreted to the periplasm, aggregation and the necessity for in vitro folding may be avoided.

The production of deglycosylated proteins in *E. coli* expression systems for in vitro biochemical and structural studies is obviously of great value; however, the proteins may not always be suitable for in vivo studies due to low biological activity. Compared to authentic proteins, nonglycosylated variants can have a reduced circulatory lifetime and can exhibit increased immunogenicity and protease sensitivity (Rasmussen, 1992). Hodgson (1993) reviews the various expression systems used by biotechnology companies and lists the therapeutic proteins in development, many of which are produced in *E. coli* and which are normally glycosylated.

PROTEIN HANDLING

Storing Purified Proteins

Purified protein should be filter sterilized prior to storage. Millex-GV 0.22-μm filters (Millipore) are based on hydrophilic membranes with low binding capacities and are recommended for most proteins. Proteins are best stored at –80°C or may be stored on ice; freezing at –20°C is not recommended. Rapid freezing in small aliquots using dry ice/ethanol mixtures is preferred to slow freezing in the refrigerator. The addition of sucrose or glycerol often increases protein stability during storage and during freezing and thawing cycles (Arakawa and Timasheff, 1985; Timasheff and Arakawa, 1989). Lyophilization is best for long-term storage; however, care should be taken in choosing the protein solvent (Franks, 1993).

Promoting Protein Solubility and Stability

If the recombinant protein contains reactive unpaired sulfhydryl groups in the native conformation, 1 to 5 mM DTT should be included in the column buffers during purification. However, reductant should not be used gratuitously, as the native protein may contain intra- or intermolecular disulfide bonds, disruption of which can reduce the stability and solubility of the protein. Reductants should be included, for example, during gel filtration if dimers or higher aggregates need to be converted to active monomeric protein. The presence of intermolecular (and occasionally intramolecular) disulfide bonds can be determined analytically by SDS-PAGE under nonreducing conditions (*UNIT 6.5*): proteins are pretreated sequentially with iodoacetamide (to prevent artificial disulfide exchange) and SDS in the absence of reductant. The use of reductants can best be rationalized once the native protein has been characterized.

EDTA (1 to 5 mM) is often included in buffers to remove heavy metals that can catalyze oxidative processes and to inhibit certain proteases. It should be noted that EDTA will bind to anion exchangers (Scopes, 1994).

Other components often added to buffers to promote protein solubility during purification

ECU IASH CENTRAL UNIVERSITY LIBRARY

include nonionic or zwitterionic detergents, low concentrations of urea (1 to 2 M), and salt (0.5 to 1 M NaCl). These additives are compatible with ion-exchange chromatography, except for high salt concentrations, which are compatible with hydrophobic-interaction chromatography (*UNIT 8.4*), affinity chromatography (Chapter 9), and gel-filtration chromatography (*UNIT 8.3*). Solvent pH is one of the most important variables for maintaining protein solubility; in general, proteins are least soluble at or near their isolectric points.

Preventing Contamination

Precautions to prevent contamination of the protein of interest are as follows:

1. To avoid cross-contamination, especially from other recombinant proteins, reserve one set of chromatography resins for the purification of each protein. If this is not possible, or if expensive prepackaged matrices are used, be sure to clean resins thoroughly after each use; check the manufacturer's recommendations and be aware of the chemical stability of the resin, especially for extremes of pH.
2. Store resins with preservatives (e.g., sodium azide) and avoid storage in phosphate buffers, which provide a good medium for bacterial growth.
3. To generate reproducible protocols using ion-exchange methods, monitor the pH and conductivity of all buffers and column effuents (the latter ideally in-line).
4. Avoid protein cross-contamination in concentration equipment such as stirred ultrafiltration cells with ultrafiltration membranes.
5. Keep pH and conductivity probes scrupulously clean, especially when used with solutions containing proteases. Likewise, observe care when using cuvettes for UV measurements.
6. Avoid rigorous stirring of protein solutions to prevent shear denaturation, and handle soft agarose-based column matrices carefully to prevent bead fragmentation.

Removing Pyrogens

Recombinant proteins used for in vivo studies should be free of endotoxins (pyrogenic lipopolysaccharide from the bacterial outer membrane). Pyrogens can be detected using the sensitive *Limulus* amoebocyte lysate (LAL) assay with kits available from Sigma and other suppliers, and they can be removed using polymin B immobilized on agarose (Detoxi-Gel from Pierce). For further discussion of pyrogens and nucleic acid contamination, see Walsh and Headon (1994b).

SCALE OF OPERATIONS AND AIMS OF PURIFICATION

Determining Scale

The amount of protein required and the level of purity will vary dramatically from laboratory to laboratory and study to study. The following guidelines will help in planning a stategy.

If a Coomassie blue-stained band corresponding to the expressed protein is observed on one-dimensional SDS-PAGE analysis of a whole-cell extract, then the protein constitutes at least 0.5% to 1% of the total protein. Wet *E. coli* cell paste contains ~10% to 15% protein by weight (reviewed by Neidhardt, 1987). If the level of expression is low to average (e.g., 5%), then 1 g wet weight cells will contain ~5 mg recombinant protein. Hence, a cell paste of 20 to 50 g (a typical yield from a 1- to 2-liter benchtop fermentation) will contain 100 to 250 mg recombinant protein, and often 2- to 5-fold more. (Shaker flask fermentations of equivalent volumes might yield 5% or 10% of these amounts.) Thus, for soluble proteins, or insoluble ones that can be refolded (with ≥5% yield), significant amounts of protein can be obtained from relatively small fermentations. For proteins secreted into the periplasm or medium, fermentations at larger scales may be required, as expression levels are usually considerably lower than for direct expression.

Deciding the Aims of the Purification

There are obviously many reasons, both scientific and commercial, for producing purified recombinant proteins. The development of laboratory-scale purification schemes that produce a single band of protein on SDS-polyacrylamide gels should not pose major problems given the relatively high abundance of recombinant proteins in cell extracts, and assuming that protein folding has been solved. Protein present at 1% of the total cell extract requires only a 100-fold purification compared to the several thousandfold sometimes required for the purification of nonrecombinant proteins (reviewed by Stein, 1991). However, far more time and expertise may be needed to develop protocols that produce purified recombinant proteins having the physical and chemical homogeneity required for clinical-grade materials and for structural determinations.

A single band on an SDS-polyacrylamide gel may exhibit many bands on an isoelectric

BURNS / METRAL UNIVERSITY LIBRARY

focusing gel (*UNIT 7.1*). Only after detailed characterization of the isolated protein will the nature of the chemical and physical microheterogeneities be understood well enough to either prevent their occurrence or rationalize how to fractionate unmodified from modified species.

For many investigators, a primary goal is to correlate the structure of a protein with its function (and vice versa). Many proteins produced by recombinant DNA technology are present only in trace amounts in nature (e.g., interferons and other cytokines; Ealick et al., 1991), and authentic material is not available for detailed molecular characterization. Knowledge of the three-dimensional structure allows a rational approach to protein engineering and the design of drugs that modulate the biological activity of the protein. The substitution, deletion, and insertion of residues allow a structure-function hypothesis to be tested and new, sometimes improved protein variants (or mutants) to be produced.

Structural determination by X-ray diffraction requires good-quality crystals. Working out crystallization conditions may take from a few milligrams (lucky) to a hundred milligrams or more (realistic). The protein itself must usually be physically and chemically homogeneous; the presence of small amounts of unrelated *E. coli* protein impurities may interfere with crystallization. In general, physical homogeneity is more critical than chemical homogeneity. Some of the methods used to establish physical and chemical homogeneity are discussed elsewhere (Chapter 7; Jones et al., 1994). Structure determination by the X-ray method can be greatly aided by in vivo labeling of recombinant proteins with heavy atom derivatives as described in *UNIT 5.3*.

Structural determination in solution by multidimensional NMR is presently limited to proteins <30 kDa (reviewed by Clore and Gronenborn, 1994). The sample demands can be as high as several hundred milligrams, and larger proteins (>10 kDa) must be uniformly labeled with various combinations of ^{2}H, ^{13}C, and ^{15}N (the usual requirements are for protein singly labeled with ^{15}N and for protein doubly labeled with ^{15}N and ^{13}C). Labeling is achieved by growing the bacteria in minimal medium containing one or more of the following stable (nonradioactive) isotopes: $^{15}NH_4Cl$ (sole nitrogen source), [^{13}C]glucose (sole carbon source), and $^{2}H_2O$ (*UNIT 5.3*).

For NMR purposes the recombinant protein must be homogeneous and soluble at 1 to 3 mM concentrations, preferably with solvents below pH 7.0 and at temperatures above 30°C. As measurements take many hours to complete, the presence of trace amounts of proteases can ruin the entire experiment. In addition, particular attention must be paid to maintaining solvent-accessible and reactive cysteines (unpaired) in the reduced state (usually by including DTT).

Low-resolution structural studies using various biophysical methodologies (Jones et al., 1994) can be made with less material (<1 to 10 mg). Proteins for spectroscopic studies should be at least 95% pure and previously fractionated on a gel-filtration column to remove aggregated and possibility misfolded variants.

Finally, with in vivo protein labeling scenarios as described for isotopes (*UNIT 5.3*), tryptophan in recombinant proteins can be replaced by 5-hydroxytryptophan by using an *E. coli* Trp auxotroph. Protein thus labeled has a strong absorbance at 310 nm that can be exploited in structure-function studies (Laue et al., 1993).

SPECIALIZED EQUIPMENT

Breaking and Fractionating Cells

For small- to medium-scale work on a regular basis, an Aminco French press (SLM Instruments) with a continuous-fill cell is recommended (*UNIT 6.2*). This equipment is also useful for breaking yeast cells. For large-scale work (>500 ml), the Manton-Gaulin-APV homogenizer (APV Gaulin) is recommended. For further processing of cells and cell lysates (e.g., *UNITS 6.2 & 6.3*), an ultrasonic homogenizer is required. An instrument with a 400-W (or higher) capacity is recommended (Branson or other vendor).

After low-speed centrifugation using standard preparative centrifuges, high-speed centrifugation is a convenient and rapid cleanup step before column chromatography (Fig. 6.1.3). With Beckman ultracentrifuges, the 45 Ti rotor is recommended. This six-place rotor has a maximum speed of 235,000 × *g*; with thick-walled polycarbonate tubes, its capacity is ~400 ml.

Chromatographing Proteins

Most chromatography is carried out at 4°C either in a cold room or, more conveniently, in a cold cabinet in the laboratory. The basic components of a chromatography system are as follows: column, column matrix, pumps, a gradient-making device, UV/visible or other detection system, and a fraction collector.

ECU IAS/CSURA - UNIVERSITY LIBRARY

These components can be bought as units such as Pharmacia Biotech's FPLC (small- to medium-scale work) and BioPilot systems (medium- to large-scale work), or they can be assembled using individual components from various vendors. Column matrices can be purchased prepacked or as bulk media that are packed in columns by the user. Ion-exchange separations, using standard low- to medium-pressure resins (agarose/dextran/cellulose–based), require at least one narrow (2.5-cm) and one wide (5.0-cm) column with adjustable flow adapters so that the resin height can be varied between 5 and 30 cm. Gel filtration requires columns with diameters of 1.25 and 2.5 cm (5 cm for larger scale work) and lengths of 60 to 100 cm. Simple gradient makers with capacities of 150 ml to 2 liters can be purchased from Life Technologies (formerly GIBCO/BRL).

Concentrating Proteins

Stirred ultrafiltration cells are recommended for laboratory-scale work. The cells range in size from 3 ml to 2 liters and are used in conjunction with variable molecular weight cutoff membranes (Amicon). For larger volumes, both Millipore and Amicon sell various systems (see respective manufacturer's literature). For smaller volumes (0.5 to 15 ml), centrifugational concentrators are available (Amicon and others). For a review of the equipment used for protein concentration, see Harris (1989).

Making Analytical Measurements

A protein purification laboratory should have a good scanning UV/visible spectrophotometer, ideally an instrument with computerized data collection and analysis. Hewlett Packard instruments with diode array detectors are recommended for most routine work. For laboratories specializing in purifying recombinant proteins from *E. coli*, access to a spectropolarimeter (e.g., Jasco J-720) will be helpful for monitoring and developing folding protocols.

Preparation of Soluble Proteins from *Escherichia coli*

Once a suitable protein expression system involving *Escherichia coli* is developed and optimized (*UNITS 5.1 & 5.2*), large-scale production of recombinant proteins (*UNIT 5.3*) generates large quantities of culture material from which the protein of interest must be purified. Harvesting (*UNIT 5.3*) produces cell concentrate or culture medium, depending on the subcellular localization of the protein. Cell paste is the starting material for purification of proteins expressed in soluble form inside cells, such as interleukin 1β (IL-1β). Human IL-1β is a 153-residue (17.4-kDa) protein cytokine of biomedical importance that plays a central role in immune and inflammatory responses. Purification of human IL-1β is used as an example of the preparation of soluble proteins from *E. coli*.

Bacteria containing IL-1β are lysed, and the resulting supernatant is clarified to remove ribosomes and other particulate matter. The sample is then applied to an anion-exchange column to separate recombinant IL-1β from cellular contaminants, such as *E. coli* proteins, nucleic acids, and lipopolysaccharides. The sample is further purified through salt precipitation and cation-exchange chromatography, then concentrated. Finally, the IL-1β protein is applied to a gel-filtration column to separate it from remaining higher- and lower-molecular-weight contaminants, the purified protein is stored frozen or is lyophilized.

The purification protocol described is typical for a protein that is expressed in fairly high abundance (i.e., >5% total protein) and accumulates in a soluble state. With these expression levels, only about a 20-fold overall purification is required to obtain pure protein. Therefore, conventional chromatographic methods can be used, and normally only three or four purification stages are required (see Table 6.2.1 for an outline of the procedure as applied to IL-1β, including time considerations). The process can be shortened somewhat through the use of the Pharmacia Biotech BioPilot or FPLC systems (see Time Considerations).

SDS-PAGE (*UNIT 10.1*) is used to monitor column fractions for the presence of IL-1β, which is detected as a stained band (*UNIT 10.5*) at the expected 17.4-kDa location. This is common practice in recombinant protein purification, as the specific assays for many proteins, including IL-1β, are relatively complex. The original expression and fermentation experiments involving IL-1β (Wingfield et al., 1986) followed procedures similar to those given in *UNIT 5.3*.

CAUTION: Avoid direct contact with IL-1β-containing solutions. Trace material from aerosols or from hand contact can cause severe inflammation of the eyes. Safety glasses and gloves should be worn.

PURIFICATION OF A PROTEIN EXPRESSED IN *ESCHERICHIA COLI* IN A SOLUBLE STATE: INTERLEUKIN 1β

BASIC PROTOCOL

Materials

DEAE Sepharose CL-4B resin (Pharmacia Biotech)
Anion-exchange buffer (see recipe)
0.26% (w/v) sodium hypochlorite/70% ethanol *or* 5% (v/v) bleach (e.g., Clorox)/70% ethanol
E. coli cells (~50 g wet weight) from fermentation (*UNIT 5.3*) containing IL-1β
Lysis buffer (see recipe)
Bovine pancreas DNase I and RNase A (Worthington; optional, for reducing solution viscosity)

Copyright © 1995 by John Wiley & Sons, Inc.

BOWLES CENTRAL LIBRARY UNIVERSITY

2 N sodium hydroxide
Ammonium sulfate, ground with mortar and pestle
Cation-exchange buffer (see recipe)
CM Sepharose CL-4B (Pharmacia Biotech)
Cation-exchange buffer/250 mM NaCl (see recipe)
Tris base
Gel-filtration buffer (see recipe)
Ultrogel AcA54 gel-permeation resin (BioSepra)
Lyophilization buffer (see recipe; optional)

2- or 3-liter sintered glass funnel with fritted disc (coarse porosity) and 5-liter filter flask
Chromatography columns (preferably glass) with adjustable flow adapters: one (or optionally two) 5 × 50 cm and one 2.5 × 100 cm (Pharmacia Biotech, Amicon, or equivalent)
RK50 packing reservoir (Pharmacia Biotech)
Peristaltic pump, UV monitor, and fraction collector (Pharmacia Biotech or equivalent)
16 × 150–mm culture tubes
40-ml French pressure cell and rapid-fill kit (SLM-AMINCO)
Aminco laboratory press (SLM-AMINCO)
1-liter Waring commercial blender

Table 6.2.1 Outline of Interleukin β Purification[a]

Day	Steps (low pressure)	Steps (BioPilot or FPLC)
1	Preparation of DEAE Sepharose column (steps 1-3)	As for low pressure (steps 1-17)
	Cell breakage (steps 4-8)	
	Clarification of lysate (steps 9 and 10)	
	DEAE Sepharose chromatography (step 11)	
	SDS-PAGE of DEAE Sepharose fractions (step 12)	
	$(NH_4)_2SO_4$ fractionation (steps 13-15)	
	Dialysis (steps 16 and 17)	
2	CM Sepharose chromatography (steps 18-22)	Fast Flow (substitute for CM Sepharose; steps 18-21)
	SDS-PAGE of CM Sepharose fractions (step 22)	SDS-PAGE of Fast Flow fractions (steps 22)
		Concentration (step 23a)
		Superdex 75 gel filtration (substitute for Ultrogel; steps 24-26)
3	Concentration (step 23a or 23b)	SDS-PAGE of Superdex 75 fractions (step 26)
	Ultrogel gel filtration (steps 24-26)	Concentration (step 27)
4	SDS-PAGE of gel-filtration fractions (step 26)	
	Concentration (step 27)	

[a]Step numbers in parentheses refer to the Basic Protocol. Chromatography materials as well as the BioPilot and FPLC systems are from Pharmacia Biotech.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

250, 500, and 1000-ml stainless steel beakers
Ice bucket, ~4 liter
Tissue-grinder homogenizer (Polytron Model PT 10/35, Brinkmann)
Ultrasonic homogenizer, ≥400 W, with sound enclosure (Branson or equivalent)
Preparative centrifuge: Beckman J2-21M
Rotors for preparative centrifuge: Beckman JA-14 (capacity 6 × 250 ml) or JA-20 (capacity 8 × 50 ml)
Ultracentrifuge: Beckman Optima XL-90
Rotors for ultracentrifuge: Beckman 45Ti (capacity 6 × 100 ml) or 35Ti (capacity 6 × 94 ml)
Conductivity meter (Radiometer America)
Spectra/Por 1 dialysis tubing (Spectrum)
Gradient maker: Model 2000 (working volume 0.65 to 2 liters; Life Technologies)
200- or 400-ml stirred ultrafiltration cell and Diaflo ultrafilter PM10 or YM3 membranes (Amicon; optional)
Millex-GV 0.22-µm-pore-size filter units (Millipore)
10- or 20-ml syringe

Additional materials and equipment for SDS-PAGE (*UNIT 10.1*) and dialysis (*APPENDIX 3B*)

NOTE: All protocol steps are carried at 4°C unless otherwise stated. Forces for centrifugation steps refer to the maximum × *g* (i.e., centrifugal force at the bottom of the tubes).

Prepare anion-exchange column

1. Pour 400 to 500 ml DEAE Sepharose CL-4B ion-exchange resin into a sintered-glass funnel and wash with several liters water followed by 1 liter anion-exchange buffer (pH 8.5). Measure the conductivity of the starting buffer and eluted buffer to make sure they are the same before proceeding to the next step.

   The resin is supplied in 500-ml bottles as a slurry in 20% ethanol. When washing the resin, do not allow it to run dry on the filter funnel. Laboratory vacuum (e.g., water aspirator) is adequate for filtering.

2. Suspend the washed resin in anion-exchange buffer to 75% settled gel/25% buffer by volume, per manufacturer's recommendations. Degas in a filter flask and pour into a 5 × 50–cm chromatography column fitted with a filling reservoir.

   After settling, the height of the resin should be ~20 to 25 cm (390 to 490 ml packed resin). For details on packing columns, see UNIT 8.4. Because the solubility of gases decreases with increases in temperature, it is usual practice to pack the column at room temperature and then run it in a cold room or cold box.

3. Elute column with anion-exchange buffer at 100 to 150 ml/hr using a peristaltic pump. Make sure there is no compression of column contents. Monitor the absorbance of the effluent at 260 or 280 nm with a UV detector. Collect ~15-ml fractions in 16 × 50–mm culture tubes using a fraction collector. Check that the pH and conductivity of the column effluent are the same as the for anion-exchange buffer applied to the column (this indicates that the column matrix is correctly equilibrated).

   The bed height should not change significantly once the column is packed. Compression indicates that the pressure applied to the column is too high (see manufacturer's recommendations for maximum flow rates).

Break cells with a French press

4. Clean bench areas that may come in direct contact with cells with 0.26% sodium hypochlorite/70% ethanol.

BU ARTICLE CENTRAL UNIVERSITY LIBRARY

5. Assemble the French pressure cell and and chill to ~4°C either by incubation in ice or by refrigeration. Install the cell (first dried with paper towels if necessary) in the Aminco laboratory press.

It is important to cool the equipment because pressurizing will generate heat. The 20K rapid-fill French pressure cell (1-in.-diameter piston) has a capacity of 40 ml and can be continuously filled while installed on the press. Before using the pressure cell, replace the nylon ball at the end of the flow valve assembly or, at the very least, check it for distortion.

For small-scale work, a miniature French pressure cell (3/8-in.-diameter piston) with a 3.7-ml capacity is available.

6. Suspend thawed *E. coli* cells (~50 g wet weight) with 150 ml lysis buffer using a Waring blender. Place the suspension in a stainless steel beaker and homogenize with the Polytron tissue-grinder homogenizer until clumps are no longer detected.

IMPORTANT NOTE: *Wear disposable gloves and safety glasses while working with E. coli. The high-pressure homogenization may generate aerosols.*

The E. coli cells are stored frozen at –80°C as a flattened paste in heat-sealable plastic bags (UNIT 5.3). The cells are thawed at room temperature. Complete suspension of the cells with the blender is important, as any visible clumps of bacteria will block the French pressure cell. A clogged cell may have to be disassembled to clear the blockage.

7. Lyse the cells with two passes through the French press operated at 16,000 to 18,000 lb/in^2 (with the high-ratio setting, pressure gauge readings between 1011 and 1135). Chill the cell suspension to 4°C after each pass through the pressure cell by incubation on ice.

When filling the pressure cell, avoid drawing air into the cylinder to prevent foaming.

If a French press is not available, the cells can be broken by including 200 µg/ml lysozyme (Worthington) and 0.05% (w/v) sodium deoxycholate (Calbiochem) in the lysis buffer and incubating cells ~20 min at 20° to 25°C with intermittent homogenization using the tissue grinder (Burgess and Jendrisak, 1975). Cell breakage by lysozyme treatment and sonication is described in Basic Protocol 3 of UNIT 6.5.

8. Place the suspension (contained in a steel beaker) on an ice bath and, using an ultrasonic homogenizer, sonicate 5 min at full power with 50% duty cycle (on for 0.5 sec then off for 0.5 sec). While sonicating, stir the suspension using a magnetic stirrer.

IMPORTANT NOTE: *Wear sound-protection earmuffs to protect ears from ultrasonic noise. Because sonication will generate some aerosol, use the sonicator in a microbiological hood if possible.*

High viscosity reduces the rate of sedimentation of the various contaminating cellular material and thus longer (sometimes much longer) centrifugation times are required. Sonication reduces the viscosity of the suspension prior to centrifugation by shearing the released DNA and RNA. The viscosity can also be reduced by digesting the lysate 15 to 30 min at 4° to 10°C with bovine pancreas DNase I (25 to 50 µg/ml) and RNase A (50 µg/ml). If the nucleases are used, EDTA in the lysis buffer should be replaced by 5 mM $MgCl_2$ as DNase requires Mg^{2+}.

Clarify the lysate

9. Transfer sample from the beaker to centrifuge bottles and centrifuge the cell lysate 40 min at 22,000 × *g* (e.g., in a Beckman J2-21M preparative centrifuge at 12,000 rpm using JA-14 rotor or at 13,500 rpm using JA-20 rotor), 4°C. Decant the supernatants, pool, and recentrifuge 90 min at ~100,000 × *g* (30,000 rpm in Beckman Optima XL-90 ultracentrifuge using Ti45 rotor), 4°C.

Low-speed centrifugation removes unbroken cells and large cellular debris. High-speed centrifugation removes smaller particles such as ribosomes and membrane

PCU IASI / CENTRAL UNIVERSITY LIBRARY

vesicles; the Beckman 70Ti rotor (capacity 8 × 39 ml) can be used in the ultracentrifuge for smaller-scale work. Clarification of the lysate can also be carried out by salt fractionation (see Background Information, section on determining solubility, for further details).

Pellets are usually discarded immediately; but see Critical Parameters and Troubleshooting, section on protein purification for further comments.

10. Dilute the supernatant from step 6 (~160 ml) 1:2 (three-fold) with anion-exchange buffer and adjust to pH 8.5 (if necessary) with 2 N NaOH. Using a conductivity meter, measure the conductivity of the diluted supernatant. If it is higher than 5.0 to 5.3 mS/cm, reduce by dilution with water.

The conductivity of the protein solution is carefully adjusted to ensure that the proteins (in this case contaminants) are bound to the matrix. Too high an ionic strength will reduce or prevent binding.

The DEAE Sepharose column is normally prepared (steps 1 to 3) before lysis of the cells is initiated. If there are any delays in applying sample to column, store the clarified lysate at 0° to 4°C (for example, in a covered beaker or flask embedded in an ice bucket). The same applies to the other chromatographic stages.

Chromatograph cleared lysate on anion-exchange resin

11. Apply the clarified lysate (480 to 500 ml) to the DEAE Sepharose column (step 3) at 150 ml/hr and elute the column with anion-exchange buffer. Continue the elution, collecting 15-ml fractions, until the effluent absorbance is close to the baseline value.

In solutions above ~pH 7.0, IL-1β (pI 6.8) is negatively charged. Therefore, the protein should, in principle, bind to an anion exchanger (positively charged matrix) buffered at pH 8.5. In fact, under the conditions described, IL-1β is only weakly bound to the matrix, which allows for partial resolution from proteins that do not bind to the matrix. Much of the unbound protein is of high molecular weight (or highly aggregated) and is partially separated from IL-1β by the gel filtration effect of the matrix. IL-1β is therefore usually located in the latter two-thirds (~500 ml) of the column flowthrough volume.

12. Assay every second or third column fraction by SDS-PAGE (*UNIT 10.1*).

See Figure 6.2.1A for an example of results from SDS-PAGE.

For rapid analysis, use precast gels or the Hoefer Pharmacia Phast system. Alternatively, if speed of purification is important, the entire flowthrough can be used, eliminating the need to analyze separate fractions. Most protein contaminants bound to the column can be removed by step elution with 1 M NaCl in column buffer. After use, the resin should be unpacked from the column and washed on a sintered-glass funnel with 1 liter of 2 M NaCl/0.5% (w/v) Triton X-100, followed by 10 liters water. If the resin is to be stored, suspend it in 5% ethanol or 5 mM sodium azide and store at 4°C. In order to avoid potential cross-contamination, dedicate the used resin for repeat purifications of IL-1β only.

Fractionate sample with ammonium sulfate

13. Pool IL-1β-containing fractions from the DEAE Sepharose column, record the volume (~500 ml), and transfer the solution to a 1-liter beaker (preferably stainless steel). Add 30.2 g $(NH_4)_2SO_4$ per 100 ml solution at 0°C (51.3% saturation or 2 M final concentration): add powdered $(NH_4)_2SO_4$ slowly over 30 min, mixing gently with a magnetic stirrer, then allow a further 30 min of mixing.

Methods for calculating the percent saturation of ammonium sulfate solutions, which specifically refer to 0°C, have been described by Wood (1976). When using solid ammonium sulfate, calculations must include volume increases on addition of the solid to fixed volumes (as carried out above).

BOULDER / GENERAL / UNIVERSITY LIBRARY

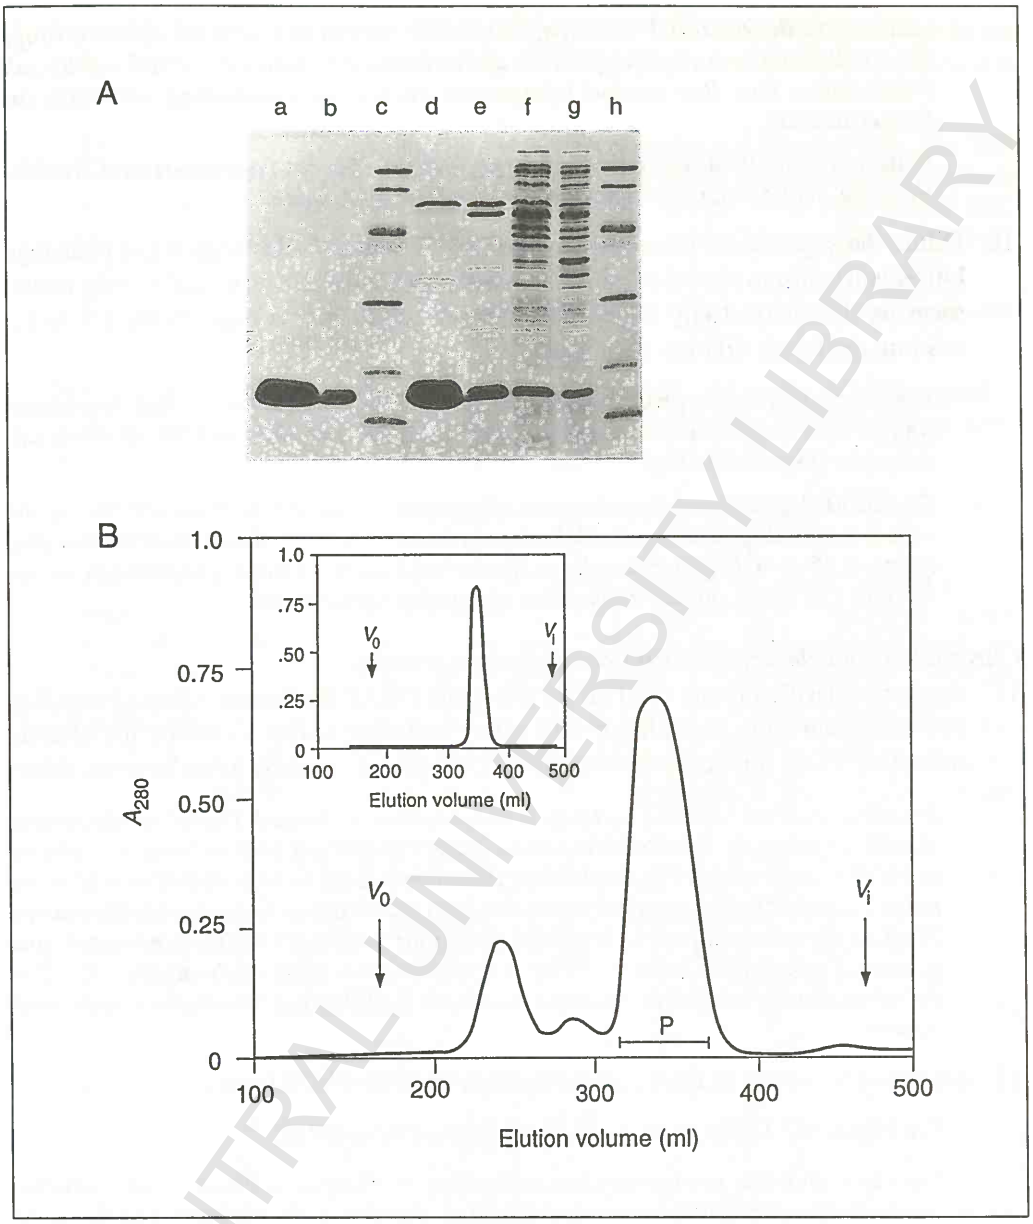

Figure 6.2.1 Purification of IL-1β. (**A**) SDS-PAGE analysis of samples at various stages. Analysis was conducted on a gel of dimensions 12 cm × 16 cm × 1.5 mm. Lane a, purified protein (100 µg loaded); lane b, purified protein (10 µg loaded); lane d, CM Sepharose pool (80%); lane e, DEAE Sepharose pool after ammonium sulfate fractionation (56%); lane f, high-speed supernatant (starting material for DEAE Sepharose column; 13.5%); lane g, cell lysate (12.0%). The percentages refer to specific IL-1β contents of the fractions determined by densitometric scanning of the Coomassie blue–stained gel lanes. Lanes c and h contain the following protein standards (low-range standards supplied by Bio-Rad) in order of increasing migration distance: phosphorylase *b* (97.4 kDa), bovine serum albumin (66.2 kDa), hen egg white ovalbumin (45 kDa), bovine carbonic anhydrase (31 kDa), soybean trypsin inhibitor (21.5 kDa), and hen white lysozyme (14.4 kDa). (**B**) Analysis of results from gel filtration on Ultrogel AcA54. The excluded volume (V_0) and the fully included volume (V_i) are indicated. Inset, analytical rechromatography of the protein from the pooled fractions (indicated P in larger chromatogram).

PCU IAS CENTRAL UNIVERSITY LIBRARY

14. Centrifuge the slightly cloudy solution 30 min at 22,000 × *g* (12,000 rpm in JA-14), 4°C. Decant the supernatant into a beaker and add an additional 17 g $(NH_4)_2SO_4$ per 100 ml solution (77% saturation or 3 M final concentration). Equilibrate with stirring and centrifuge 30 min at 22,000 × *g*, 4°C.

For the addition of $(NH_4)SO_4$ follow the same method as described in step 13.

15. Decant the supernatant and drain the pellets by inverting the tubes on a paper towel. Save the pellets.

Dialyze the fractionated sample

16. Suspend the pellets in ~300 ml cation-exchange buffer and dialyze, using Spectra/Por 1 dialysis tubing, against 5 liters cation-exchange buffer. Change the dialysis buffer at least once.

The dialysis step is conveniently performed overnight; the CM Sepharose column used in step 18 can be prepared during this period.

The dialysis tubing is prepared by heating 30 to 60 min at 90° to 95°C in 5 mM EDTA. The tubing is then washed well with water and stored in 10% ethanol at 4°C prior to use. A suitable length of tubing is filled to about one-half to three-quarters capacity with solution (to allow for expansion) and sealed with two knots at each end. Use gloves when handling the tubing, check for leaks before use, and make sure the magnetic stir-bar does not rub against the tubing. See APPENDIX 3B for further information concerning dialysis.

17. After dialysis, remove the slightly cloudy solution from the tubing and centrifuge 30 min at 22,000 × *g* (12,000 rpm in JA-14), 4°C. Save the supernatant.

Chromatograph dialyzed sample on cation-exchange resin

18. Prepare ~200 to 225 ml CM Sepharose CL-4B resin by washing on a sintered-glass funnel first with water, then with cation-exchange buffer (pH 5.7; wash as in step 1 except using different buffer). Pack the degassed resin into a 5 × 50–cm column as in step 2.

The packed column will have a bed height of ~11 to 12 cm. The comments made in the annotation to step 3 also apply here.

19. Elute the column using cation-exchange buffer at 100 to 150 ml/hr with a peristaltic pump. Monitor the column effluent at 280 or 260 nm using a suitable UV detector. Check that the pH and conductivity of the column effluent are the same as for the buffer applied to the column.

20. Check the pH and conductivity of the dialysate supernatant from step 17 and, if necessary, dilute with water so that the conductivity is in the range 1.0 to 1.2 mS/cm (at 4° to 6°C). Apply the clear solution to the CM Sepharose column at a flow rate of 150 ml/hr. When the UV absorbance of the column effluent approaches baseline, proceed to the next step.

21. Prepare a 0 to 250 mM NaCl gradient in cation-exchange buffer by adding 500 ml buffer to the inner chamber of the gradient maker and 500 ml buffer/250 mM NaCl to the outer chamber. Apply the gradient to the column at 150 ml/hr. Collect 15-ml fractions.

The total volume of the gradient is 1 liter (~4.5 column volumes).

At pH 5.7, IL-1β (pI 6.8) is positively charged and binds to the negatively charged cation-exchange resin. IL-1β is eluted from the column with ~100 mM NaCl, and it will be located in the major absorbance peak (see Wingfield et al., 1986, for figure of typical elution profile).

BOURNEMOUTH UNIVERSITY LIBRARY

22. Monitor the progress of the gradient using an in-line conductivity meter positioned after the absorbance flow cell. Assay column fractions for IL-1β by SDS-PAGE (*UNIT 10.1*) and pool fractions containing IL-1β.

Deciding what fractions to pool is dictated by the fact that the remaining purification stage is gel filtration, a method that will not remove contaminants with sizes close to that of IL-1β (17.4 kDa). As IL-1β is a well-expressed protein (>5% total protein), one can afford to be conservative and pool for purity rather than yield.

The used CM-Sepharose matrix can be cleaned up and stored as described in the annotation to step 12.

CM Sepharose Fast Flow or SP Sepharose FF (a strong cation exchanger; both resins are also from Pharmacia Biotech) can be used instead of CM Sepharose CL-4B. Similar results are obtained with either matrix, with the advantage of faster flow rates.

Concentrate the proteins

23a. *To concentrate proteins by ultrafiltration:* Adjust the CM Sepharose pool (150 to 250 ml) to pH 7.5 with Tris base. Assemble a 200- or 400-ml stirred ultrafiltration cell containing a washed ultrafilter membrane, either YM3 (3-kDa cutoff) or PM10 (10-kDa cutoff). Pressurize the cell with nitrogen according to manufacturer's recommendations. Collect the effluent from the cell into a measuring cylinder and occasionally record the absorbance at 280 nm to check that the membrane is not leaking. When the volume remaining in the cell is ~15 ml, depressurize the cell and carefully remove the solution using a Pasteur pipet with a small length of polyethylene tubing attached to the end so as not to scratch the membrane. Use ~3 ml gel-filtration buffer to wash the membrane, adding washings to the main concentrate.

Exposure to solutions below pH 4.5 and above pH 10.5 to 11.0 often causes protein denaturation. Hence, when adjusting the pH of protein solutions, there is less chance of overshooting the required pH by using concentrated buffer components instead of pure acid or base. For example, Tris base is used rather than dilute NaOH.

Select the ultrafiltration membrane pore size based on the size of the protein. The membrane can be reused; store in 5% ethanol at 4°C. It is good practice to reserve a membrane for use with a particular protein (compare comment on resin usage) and to wash the concentration cell carefully after use.

23b. *To concentrate proteins by salt precipitation:* Adjust the CM Sepharose pool to pH 7.5 with Tris base and slowly add 53.9 g $(NH_4)_2SO_4$ per 100 ml solution at 0°C (82.2% saturation or 3.2 M final concentration). Follow the basic salt precipitation method (steps 13 to 15) and suspend the pellets in 18 to 20 ml gel-filtration buffer.

Conduct gel-filtration chromatography

24. Prepare ~480 ml Ultrogel AcA54 resin by washing on a sintered-glass funnel with water, then gel-filtration buffer (as in step 1); suspend washed resin in gel-filtration buffer to 75% settled gel/25% buffer by volume and degas (step 2). Pour a slurry of degassed resin into a 2.5 × 100–cm chromatography column fitted with a filling reservoir. Pack the column at ~35 ml/hr.

UNITS 6.3 & 8.3 should be consulted for further details on the preparation and elution of gel-filtration columns. The column should be prepared in advance so that the protein samples can be applied as soon as the concentration step is completed.

The resin should be free-flowing yet concentrated enough to produce a packed bed with one pouring. A freshly packed gel-filtration column can be checked for packing irregularities by prerunning the column with a few colored markers. Blue dextran will be excluded from the gel matrix and will elute at the void volume (V_0, which equals 30% to 35% of the total column volume); cytochrome c (red; 12.4 kDa) will elute close

PCU IASI CENTRAL UNIVERSITY LIBRARY

to the expected position of IL-1β; and potassium dichromate (yellow) will be fully included in the gel matrix and will elute at the included volume (V_i ~480 ml).

Superdex 75 gel-filtration matrix (Pharmacia Biotech) can be substituted for Ultrogel AcA54. The former allows higher flow rates and thus is more compatible with the FPLC and BioPilot systems. Both Superdex and the cation-exchange Fast Flow resins mentioned above can be purchased in various prepacked columns that are useful for method development.

25. Filter the concentrated protein using a Millex-GV 0.22-μm filter unit attached to a 10- or 20-ml syringe and apply to the gel-filtration column. The sample can be applied either directly to the top of the column using a Pasteur pipet (care is required to prevent breaking the tip and contaminating the column) or via a three-way valve and syringe without removing the top flow adapter.

The volume of sample applied to the column (20 ml) represents ~4% of the total column volume. For columns with different dimensions, apply the same proportionate volume of sample. The column should be ≥60 cm long. For analytical separations, the sample volume should not exceed 2.5% of the column volume.

26. Elute the column at 35 ml/hr with gel-filtration buffer and collect 10-ml fractions. The major eluting peak contains the IL-1β; monitor the fractions by SDS-PAGE (*UNIT 10.1*) and pool fractions that contain pure protein. Save side fractions that contain small amounts of contaminants; this material can be rechromatographed after concentration as described in step 23a or 23b.

See Figure 6.2.1A for an example of results from SDS-PAGE.

Once the sample has been run into the column, it can be eluted with any buffer or even with a suitable column storage solvent such as 5 mM sodium azide in water.

Concentrate and store purified protein

27. Concentrate the purified protein, if required, by ultrafiltration (see step 23a). Determine the protein concentration of purified IL-1β by measuring absorbance at 280 nm.

A molar absorbance coefficient (ε) of 10.61 mM^{-1} cm^{-1} is used. This corresponds to an absorbance of 0.63 for a 1 mg/ml solution using a 1-cm-path length cell.

28. For short-term storage (≤12 months), filter the protein with a Millex-GV 0.22-μm filter unit, divide the solution into sterile plastic vials, and freeze aliquots rapidly with dry ice/ethanol. Store at –80°C. For long-term storage of IL-1β (>12 months), lyophilize the protein. Dialyze the sample using a volatile buffer such as 50 mM ammonium bicarbonate or a nonvolatile buffer such as lyophilization buffer.

To circumvent the dialysis step, the phosphate-based lyophilization buffer can be used for gel filtration instead of the Tris·Cl gel-filtration buffer.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX. Buffer pH and conductivities are for solutions at 4° to 6°C. Units of conductance are given in siemens ($S = \Omega^{-1}$).

***Anion-exchange buffer** (50 mM Tris·Cl, pH 8.5)*

Dilute 1 M Tris·Cl, pH 8.0 20-fold with water and adjust to pH 8.5 with NaOH. Make immediately before use.

Conductivity of the solution is 1.57 mS/cm.

B. C. I. IAȘI

BCU IAȘI / CENTRALA UNIVERSITARĂ LIBRARY

Cation-exchange buffer, 10× (15 mM sodium phosphate, pH 5.7/1 mM sodium azide)

19.4 g $NaH_2PO_4 \cdot H_2O$
1.4 g $Na_2HPO_4 \cdot 2H_2O$
0.65 g sodium azide
H_2O to 1 liter
Store up to 1 month at 4°C
Dilute 10-fold immediately prior to use

Conductivity of the solution is 0.9 mS/cm. Sodium azide is an antibacterial agent.

Cation-exchange buffer (1×)/250 mM NaCl

14.61g NaCl
100 ml 10× cation-exchange buffer (see recipe)
H_2O to 1 liter

***Gel-filtration buffer** (100 mM Tris·Cl, pH 7.5/1 mM sodium azide)*

Dilute 1 M Tris·Cl, pH 8.0 10-fold with water and adjust to pH 7.5 with HCl. Add sodium azide from a 1 M stock solution (65 g/liter). Make immediately before use.

***Lyophilization buffer** (25 mM sodium phosphate, pH 7.5/0.5 mM sodium azide)*

2.2 g $NaH_2PO_4 \cdot H_2O$
11.9 g $Na_2HPO_4 \cdot 2H_2O$
1.3 g sodium azide
H_2O to 4 liters
Make fresh and use immediately

Usually, 2 liters is required for dialysis, with one buffer change (4 liters total). Gel filtration requires smaller volumes.

Lysis buffer

100 mM Tris·Cl, pH 8.0
2 mM EDTA, pH 8.0
5 mM benzamidine·HCl (780 mg/liter)

Make immediately prior to use; alternatively, make ahead of time and store up to several days at 4°C.

Conductivity of the solution is 1.57 mS/cm.

It should be noted that a 1°C decrease in temperature increases the pH of the Tris buffer by ~0.03 pH units. Both Tris·Cl and EDTA stock solutions are commercially available (e.g., Life Technologies).

Benzamidine·HCl is a water-soluble serine protease inhibitor. An alternative is 50 μM 4-(2-aminoethyl)benzenesulfonyl fluoride hydrochloride (AEBSF; Perfabloc SC, Boehringer Mannheim), a water-soluble inhibitor with the same spectrum of activity as phenylmethylsulfonyl fluoride (PMSF).

COMMENTARY

Background Information

Expression of soluble proteins

The basic stages involved in preparing soluble proteins from *E. coli* are achieving protein expression, harvesting and breaking cells (or collecting culture medium, in the case of secreted proteins), purifying proteins, and characterizing the purified protein. Choices that must be made at each stage are briefly reviewed.

Optimizing the expression system

The basic requirements for protein expression in *E. coli* are discussed in UNIT 5.1. Experience has shown that it is usually possible to express any given protein in *E. coli*, but whether the protein will be expressed in a soluble and unmodified state is unpredictable. Tinkering with the various elements of the expression plasmid, changing the *E. coli* host strains, and altering the fermentation conditions are carried out to optimize the expression

PCU IASI / CENTRAL UNIVERSITY LIBRARY

of unmodified soluble protein (*UNIT 5.1*). Use of secretion vectors and fusion protein constructs to prevent aggregation has been discussed elsewhere (*UNITS 5.1 & 6.1*). Even if efforts to express soluble protein fail and inclusion bodies are produced, there is often a good chance that the protein can be extracted and folded into native protein (see *UNITS 6.4 & 6.5*).

There are situations where the intrinsic properties of a protein can preclude its expression in a soluble and stable form. Examples include the following: (1) individual subunits of a heterodimer, which may be unstable and may degrade or aggregate when expressed separately (coexpression of the subunits may solve the problem; Nash et al., 1987); (2) proteins derived from activated precursors (*UNIT 6.4*; Hlodan and Hartl, 1994); and (3) proteins in which the native (authentic) sequences have been modified by site-directed mutagenesis (Chrunyk et al., 1993). It is worth noting that the solubility of proteins that are otherwise insoluble or poorly soluble can, conversely, sometimes be improved by site-directed mutagenesis (Dyda et al., 1994).

Once conditions have been found that result in the expression of soluble protein, the next hurdle is to recover the protein in an unmodified form. Avoiding proteolysis and chemical modification during the isolation process is crucial.

Breaking cells

Methods for breaking cells or selectively extracting proteins are reviewed in *UNIT 6.1*. In the protocol for purifying human IL-1β, cells are disrupted with a French press. This method is the most efficient way to break *E. coli* cells and is the method of choice. The equipment, however, requires dedicated laboratory space and may be expensive for some laboratories. Cell breakage with lysozyme (*UNIT 6.5*) and/or sonication is also frequently used; such methods are especially suited to small-scale work (reviewed by Hopkins, 1991).

It is important to consider whether the cell breakage method influences the final solubility and stability of the recombinant protein in the cell lysates. A soluble recombinant protein constituting ~12% of the total bacterial protein will be present in the cytoplasmic space at a concentration of at least 30 mg/ml, assuming a total protein and RNA concentration in the cytoplasm of ~340 mg/ml in nontransformed cells (Zimmerman and Trach, 1991) and a 2.7:1 weight ratio of protein to RNA (Neidhart, 1987). Cell breakage can be expected to increase the solubility of the recombinant protein by a dilution effect (discussed by Zimmerman and Trach, 1991). Cell lysis procedures, however, especially when mechanical shear is used (e.g., French press and sonication), can produce local heating that may have a denaturing effect and lead to aggregation. Mechanical shearing will also be expected to decrease the size of nucleic acids and release polyanionic lipopolysaccharides; both classes of coumpounds can bind nonspecifically to proteins, especially basic proteins, thereby reducing their solubility. Including detergents in the lysozyme treatment may also release potent membrane-bound proteases.

Despite these potential pitfalls, the recovery of soluble protein is usually not dramatically influenced by the cell breakage method, but there is always the potential that it might be. Protein recovery as a function of cell breakage methodology is rarely systematically studied or reported. Johnson and Hecht (1994) reported that freezing and thawing of cells selectively releases recombinant proteins located in the cytoplasm. The freeze-thaw procedure, in principle, should be the best method for releasing soluble proteins in an unmodified state, but its general applicability remains to be seen.

Determining solubility

The solubility of recombinant protein in the cell lysate or extract is usually established by differential centrifugation (*UNITS 6.1 & 5.3*). Alternatively, the extract can be clarified by filtering and applied to a small gel-filtration column. An HPLC or FPLC gel-filtration separation in conjunction with a rapid screening method for assaying column fractions (e.g., SDS-PAGE using PhastSystem from Hoefer Pharmacia) can produce a determination of both solubility and size distribution in ~2 hr or less.

Purifying protein

There are many approaches to purifying proteins, such as expressing fusion proteins that contain engineered affinity handles or tags (see *UNITS 5.1 & 6.1* for further details). Most soluble proteins that are well behaved—i.e., do not contain excessive charge heterogeneity—are non-self-associating and can often be purified by two stages of ion-exchange chromatography and one or more polishing steps, one of which should be gel filtration. The basic approach is outlined in Figure 6.1.3. The purification of human IL-1β is a typical example. Specific accounts of the various chromatographic methods are found in Chapters 8 and

BOULDER LIBRARY UNIVERSITY

9; Scopes (1993) particularly emphasizes first principles.

Characterizing protein

Once a protein has been purified, it is usually characterized (Chapter 7) in order to establish chemical homogeneity (primary sequence) and physical homogeneity (size and conformation). Not only is this information required for a fundamental description of the protein, but it will also give insights on how best to rationalize the purification process. Moreover, the detection of certain heterogeneities may give clues on how to avoid their occurrence. For example, chemical modifications such as deamidation may be prevented by changing one or more purification steps that expose the protein to extremes of pH. Other modifications that arise from construction of the expression plasmid itself, once recognized, can often be fixed.

Characteristics of recombinant and authentic interleukin 1β

The cytokine IL-1β and the closely related IL-1α are synthesized mainly by monocytes and mononuclear cells as 31-kDa cytoplasmic precursor proteins (reviewed by Dinarello, 1989). A unique cytoplasmic cysteine protease (IL-1β-converting enzyme, or ICE) cleaves the IL-1β precursor in half, generating the mature form of the protein comprising the C-terminal 153 residues. The biological activities of IL-β (and IL-1α) are initiated by interaction with either type I or type II cellular receptors (McMahan et al., 1991). Both receptors have three immunoglobulin-like extracellular ligand-binding domains and single membrane-spanning segments. Another form of IL-1, the interleukin 1 receptor antagonist (IL-1ra), is a natural competitive antagonist of IL-1β.

Authentic IL-1β been isolated from human monocyte cell cultures by HPLC using anion-exchange and gel-filtration (or reversed-phase) matrices. A 3000-fold purification was required to obtain 16 μg protein from 5 liters of cell culture extract (Gery and Schmidt, 1985). The authentic protein was established to be a non-glycosylated monomer (~18 kDa), with a pI of 6.8 and containing a single N-terminal sequence (AlaProValArg) as predicted by the DNA coding sequence.

The recombinant protein produced in *E. coli* has the same properties as the natural product except that N-terminal heterogeneity is often observed. The recombinant protein usually contains a mixture of forms with Met (20%), Ala (67%), or Pro (13%) as the N terminus. The Met form is derived by incomplete processing of the initiating Met, and the Pro form is due to cleavage of the authentic N-terminal Ala by *E. coli* protease. Despite the slight differences among the recombinant variants, partial or complete separations have been achieved (Wingfield et al., 1987; Yem et al., 1988).

Both the crystal structure of IL-1β (Priestle et al., 1988) and its nuclear magnetic resonance (NMR) structure in solution (Clore et al., 1991) have been determined using material purified by the protocol described here. For some NMR studies it was necessary to produce material with a single N terminus, and this was fortuitously achieved by replacing the N-terminal Ala residue with a Cys residue. Purified protein from cells expressing the mutant (N-terminal CysProValArg) contain only N-terminal Pro. It should be noted that deletion of the first four residues of IL-1β has no effect on activity; however, the presence of the unprocessed Met reduces receptor binding 10-fold.

Interleukin 1β does not contain a disulfide—the cysteines are either buried (Cys-71) or partially buried (Cys-8)—so there is no need to include reductants in column buffers. As mentioned earlier, the authentic protein is non-glycosylated even though there is a potential N-glycosylation site (-Asn^{7}-Cys^{8}-Thr^{9}-) near the N terminus. Interestingly, when IL-1β is expressed in yeast, equal amounts of N-glycosylated (21 kDa) and nonglycosylated protein (17 kDa) are produced (Livi et al., 1991).

Other approaches to purifying recombinant interleukin 1β

Because of the biomedical importance of IL-1β, several reports have described expression and purification of the protein. Some examples are discussed.

Kronheim et al. (1986) acidified *E. coli* cell lysates to pH 4 and thus precipitated ~70% of the total protein while most of the IL-1β remained soluble. IL-1β was further purified by cation-exchange, anion-exchange, and dye-matrix chromatographies (*UNITS 8.2 & 9.2*); ~200 mg protein was recovered from 2.5 liters of culture. The noteworthy feature of this method is the acid precipitation stage. Extracts of *E. coli* contain predominately negatively charged (anionic) proteins: 60% have pI values between 5.0 and 6.0 and 80% between 4.5 and 6.7 (Sherwood, 1992). Adjustments of cell extracts to pH 5.0 and below thus result in isoelectric precipitation of substantial amounts of *E. coli* protein. This is a useful purification step as long

PCU IASRI CENTRAL UNIVERSITY LIBRARY

as the recombinant protein remains soluble (or does not coprecipitate) under the conditions.

In another approach, Meyers et al. (1987) carried out ammonium sulfate fractionation directly on the *E. coli* extract. The IL-1β protein was recovered in the fraction corresponding to 50% to 80% saturation. After desalting, the protein was further purified by ion-exchange (cation and anion) and gel-filtration chromatographies; ~400 mg protein was recovered from 250 g wet weight cells.

The high-speed centrifugation step used to remove particulate material (see Basic Protocol, step 6) can often be replaced by salt fractionation. For IL-1β, advantage can be taken of the fact that a relatively high $(NH_4)_2SO_4$ concentration is required to precipitate the protein. The disadvantage of using this approach early in the purification is that the protein must be desalted before being applied to an ion-exchange column.

Finally, it is of interest to note that IL-1β can be released from *E. coli* cells by osmotic shock treatment (Joseph-Liauzun et al., 1990). It is well known that certain *E. coli* cytoplasmic proteins, including thioredoxin, can be released by osmotic shock.

Scale of procedure

The Basic Protocol described starts with 50 g cell paste and yields ~400 mg pure IL-1β. For smaller (1 to 5 g) or larger (100 g) cell quantities, the method can be adapted by simply reducing or increasing, respectively, the cross-sectional area of the chromatography columns. For example, for 5 g cells, the diameters of the DEAE and CM Sepharose CL-4B columns are reduced to 2.5 cm, with column lengths of 20 and 10 cm, respectively. This results in 1:4 reductions in the resin volumes compared to those for the protocol utilizing 50 g cells. The original gel-filtration column can be used (2.5 × 100 cm); however, the volume of ~1:4 sample applied should be reduced to 8 to 10 ml. Alternately, a column of about the same length (60 to 100 cm) but smaller diameter (e.g., 1.25 cm) should be used. For discussion on scaling up column chromatography procedures, see *UNIT 8.3* (Strategic Planning and Scopes, 1993).

Critical Parameters and Troubleshooting

High-level protein expression with good cell yield (*UNITS 5.1-5.3*) is required to obtain reasonable amounts of pure protein. This is obviously true no matter how efficient (or inefficient) the purification protocol. Once the host/vector system and the fermentation conditions have been optimized and, equally important, standardized, the level and solubility of recombinant protein in the starting material should be consistent. However, it is sensible to check both the expression level and solubility before starting each protein purification. The expression level can usually be monitored by SDS-PAGE; *UNIT 5.2* describes how to prepare samples for analysis by SDS-PAGE, and *UNIT 10.1* gives electrophoresis procedures. Solubility can be easily monitored by breaking a small amount of cells (≤1.0 g) by sonication (*UNIT 5.3*) or by treating cells with lysozyme (*UNIT 6.5*) and microcentrifuging the resulting cell lysate to judge whether the protein is highly aggregated.

There are many reasons why protein expression may not be as high as anticipated and, worse, why the expressed protein may switch from being soluble to insoluble. For example, faulty pH control during the fermentation may cause insolubility. Whatever the situation, one should be in a position to rationally decide whether to continue with the purification or repeat the initial fermentation.

If the protein expression level is normal (>5%) and the protein has accumulated in a soluble state, implementing the Basic Protocol, which uses only standard purification methods, should be trouble-free. Common mistakes involve buffer preparation and other trivial errors such as pooling the wrong column fractions. As discussed later, do not discard column fractions until they have been completely analyzed.

A classic purification table (see for example, Table III.1 in Dixon and Webb, 1979), has not been presented, as the biological activities of IL-1β could not be measured reliably in crude *E. coli* cell extracts by assays available to the author when the method was developed (Wingfield et al., 1986). As is often the case with proteins requiring complex biological assays, protein size analysis by SDS-PAGE is used to follow purification. During the initial stages, it is of course necessary to confirm the identity of the particular band one is following, and this can be accomplished by eluting or blotting the protein from SDS-polyacrylamide gels and performing N-terminal amino acid sequence analysis. Immunoblotting with specific antibody can be used to monitor protein purification when the recombinant protein is in low abundance (e.g., for secreted proteins in the cell medium). Finally, it should be noted that several manufacturers (e.g., R&D Systems and Genzyme) now supply assay kits for many cytokines, including IL-1β.

ROSWELL PARK CANCER INSTITUTE LIBRARY

Cell breakage

Efficient cell breakage should be trouble-free as long as the French press is operated in accordance with the manufacturer's instructions. It takes a little practice to operate the flow valve. The aim is to generate as high a flow rate as possible while maintaining a pressure gauge reading of ~1000. If the flow rate is too fast, the pressure reading will drop and unbroken cells will pass into the flow stream. Toward the end of the run, the flow rate should be reduced, as it becomes difficult to control the pressure. After use the French pressure cell should be cleaned and dried, and the flow valve ball should be replaced. Store the cell at 4°C.

Protein purification

In general, troubleshooting a purification method will be much easier if fractions are not discarded until the appropriate monitoring of the purification steps is complete. When using an established method, fractions from a chromatographic run are frequently pooled on the basis of absorbance only and the remainder quickly discarded. Ammonium sulfate supernatants or pellets are often discarded on the basis of previous fractionation behavior or pilot-scale work. As stated, do not discard any fractions until they have been checked, usually by SDS-PAGE. If there has been a problem, it can usually be easily sorted out if all the fractions from the various stages are still available. If in doubt about conditions for storing fractions, freeze selected fractions at as low a temperature as possible (ideally –80°C) and discard when appropriate. When freezing material, it is worthwhile to take the extra effort to dispense small samples (<1 ml) into microcentrifuge tubes amenable for rapid analysis, if necessary, to avoid having to thaw large volumes merely to take 10 µl for SDS-PAGE.

For reproducible results, careful recording of the pH and conductivity of starting buffers, protein solutions, and column eluents is necessary. For example, if the protein does not bind to the cation exchanger (step 19), the ionic strength of the sample or column buffer may be too high. Alternatively, the buffer pH may be too high. Errors of this kind are avoided by simply measuring the conductivity and pH of all solutions at each stage. Other precautions and critical steps relating to chromatography procedures are mentioned in Chapters 8 and 9.

Anticipated Results

Purification results in recovery of ~8 mg purified protein per gram wet weight cells. That result is based on a 10% expression level; IL-1β expression levels of 10% to 15% are routinely obtained with the expression system previously described (Wingfield et al., 1986). With a 1.5-liter fermenter, at least 50 g wet weight cells/liter can be obtained using a standard complex medium (*UNIT 5.3*). Thus, ~400 mg protein is obtained from 1 liter of culture, and optimal conditions can lead to nearly twice that amount. The yield corresponds to an overall recovery of ~60% of the IL-1β originally in the cells.

Figure 6.2.1 illustrates the protein content at various purification stages. The starting material for the final stage of gel filtration (Fig. 6.2.1A, lane d) is mainly contaminated with *E. coli* proteins >44 kDa in size, and these are easily separated from the IL-1β protein (17.4 kDa) by gel filtration. Analytical rechromatography of the protein from the pooled fractions (indicated P in Fig. 6.2.1B) reveals a single symmetrical peak indicative of purity and physical homogeneity (Fig. 6.2.1B inset). A typical cation-exchange chromatogram for the purification appears elsewhere (Wingfield et al., 1986).

Time Considerations

Because IL-1β appears to be stable against proteolytic degradation and other chemical modications during purification, the speed of purification was not critical in this case. The low-pressure chromatographic method described in the Basic Protocol requires ~4 days, which can be shortened to ~3 days using the Pharmacia Biotech BioPilot or FPLC systems in conjunction with matrices that allow faster flow rates. The times required for purification whether using low-pressure chromatography (as described in the Basic Protocol) or medium-pressure chromatography in the FPLC or BioPilot systems are summarized in Table 6.2.1.

Preparation and Extraction of Insoluble (Inclusion-Body) Proteins from *Escherichia coli*

High-level expression of many recombinant proteins in *Escherichia coli* leads to the formation of highly aggregated protein commonly referred to as inclusion bodies (*UNITS 5.1 & 6.1*). Inclusion bodies are normally formed in the cytoplasm; alternatively, if a secretion vector is used, they can form in the periplasmic space.

Inclusion bodies recovered from cell lysates by low-speed centrifugation are heavily contaminated with *E. coli* cell wall and outer membrane components. The latter are largely removed by selective extraction with detergents and low concentrations of either urea or guanidine·HCl to produce so-called washed pellets. These basic steps result in a significant purification of the recombinant protein, which usually makes up ~60% of the washed pellet protein. The challenge, therefore, is not to purify the recombinant-derived protein, but to solubilize it and then fold it into native and biologically active protein.

Basic Protocol 1 describes preparation of washed pellets and solubilization of the protein using guanidine·HCl. The extracted protein, which is unfolded, is either directly folded as described in *UNIT 6.5* or further purified by gel filtration in the presence of guanidine·HCl as in Basic Protocol 2. A support protocol describes the removal of guanidine·HCl from column fractions so they can be monitored by SDS-PAGE (*UNIT 10.1*).

PREPARATION AND EXTRACTION OF INSOLUBLE (INCLUSION-BODY) PROTEINS FROM *ESCHERICHIA COLI*

BASIC PROTOCOL 1

Bacterial cells are lysed using a French press, and inclusion bodies in the cell lysate are pelleted by low-speed centrifugation. The pellet fraction is washed (preextracted) with urea and Triton X-100 to remove *E. coli* membrane and cell wall material. Guanidine·HCl (8 M) and dithiothreitol (DTT) are used to solubilize the washed pellet protein. Extraction with the denaturant simultaneously dissociates protein-protein interactions and unfolds the protein. As a result, the extracted protein consists (ideally) of unfolded monomers, with sulfhydryl groups (if present) in the reduced state.

Materials

E. coli cells from fermentation (*UNIT 5.3*) containing the protein of interest
Lysis buffer (see recipe)
Wash buffer (see recipe), with and without urea and Triton X-100
Extraction buffer (see recipe)

250- and 500-ml stainless steel beakers
0.22-μm syringe filters (e.g., Millex from Millipore)
20-ml disposable syringe

Additional equipment for breaking cells, homogenizing cells and pellets and centrifuging at low and high speeds (*UNIT 6.2*)

Break cells and prepare clarified lysate

1. Place thawed *E. coli* cells in a stainless steel beaker. Add 4 ml lysis buffer per gram wet weight of cells. Keep bacterial cells cool by placing the beaker on ice in an ice bucket.

The cells can be pretreated with lysozyme prior to lysis in the French press. Lysozyme treatment involves incubating cells ~20 min at 20° to 25°C in lysis buffer supplemented

Copyright © 1995 by John Wiley & Sons, Inc.

BOWLING GREEN STATE UNIVERSITY LIBRARY

with 200 μg/ml lysozyme, with intermittent homogenization using a tissue grinder. It should be emphasized that this optional step is carried out before French press breakage and is not simply an alternative method of cell breakage (compare the comments made in the annotation to step 4 of UNIT 6.2). Its purpose is to aid removal of the peptidoglycan and outer membrane protein contaminants during the washing steps (steps 6 to 9; for further details see UNIT 6.1 and Fig. 6.1.5). An example of this approach is given in Basic Protocol 1 of UNIT 6.5.

2. Suspend cells using a Waring blender and homogenize using the Polytron tissue-grinder homogenizer until all clumps are disrupted, as described in *UNIT 6.2*, step 3.

3. Lyse cells with two passes through the French pressure cell operated at 16,000 to 18,000 lb/in^2 (with the high-ratio setting, pressure gauge readings between 1011 and 1135), chilling the cell suspension to 4°C after each pass, as described in *UNIT 6.2*, steps 2 and 4.

4. Reduce the viscosity of the suspension by sonicating 5 min at full power with 50% duty cycle (on for 5 sec, off for 5 sec) using an ultrasonic homogenizer, as described in *UNIT 6.2*, step 5.

5. Clarify the lysed cell suspension by centrifuging 1 hr at 22,000 × *g* (12,000 rpm in a JA-14 rotor in a Beckman J2-21M centrifuge), 4°C.

   Unbroken cells, large cellular debris, and the inclusion body protein will be pelleted.

   The JA-14 rotor uses 250-ml centrifuge bottles. For processing smaller volumes the Beckman JA-20 rotor (or equivalent) with 50-ml tubes can be used, at 13,500 rpm (22,000 × g).

   The procedure for dealing with insoluble inclusion-body proteins now diverges from that for purifying soluble proteins (UNIT 6.2).

Prepare washed pellets

6. Carefully pour off the supernatant from the pellet. Using a tissue homogenizer, suspend the pellet with 4 to 6 ml wash buffer per gram wet weight cells.

   Complete homogenization of the pellet is important to wash out soluble proteins and cellular components. Removal of cell wall and outer membrane material can be improved by increasing the amount of wash solution to 10 ml per gram cells.

   The concentration of urea and Triton X-100 in the wash buffer can be varied. The urea concentration is usually between 1 and 4 M; higher concentrations may result in partial solubilization of the recombinant proteins. The usual detergent concentration is 0.5% to 5%. Triton X-100 will not solubilize inclusion body proteins; it is included to help extract lipid and membrane-associated proteins.

7. Centrifuge the suspension 30 min at 22,000 × *g* (12,000 rpm in JA-14), 4°C. Discard supernatant and, using the tissue homogenizer, suspend the pellet in 4 to 6 ml wash buffer per gram wet weight of cells.

8. Repeat step 7 two more times.

   If the supernatant is still cloudy or colored, continue washing the pellet until the supernatant is clear.

9. Suspend the pellet with wash buffer minus the Triton X-100 and urea, using 4 to 6 ml buffer per gram wet cells. Centrifuge 30 min at 22,000 × *g* (12,000 rpm in JA-14), 4°C.

   The final wash removes excess Triton X-100 from the pellet.

PCU IASI - CENTRAL UNIVERSITY LIBRARY

If necessary the washed pellets can be stored at –80°C. It is better to store material at this stage rather than after the extraction stage (see comments to step 13).

Extract recombinant protein from washed pellets with guanidine·HCl

10. Using the tissue homogenizer, suspend the pellet with guanidine·HCl-containing extraction buffer. Use 0.5 to 1.0 ml buffer per gram wet weight of original cells if the extract will be subjected to gel filtration, and 2 to 4 ml buffer if the extract will be used in protein folding procedures. Perform this step at room temperature.

    To estimate the amount of recombinant protein in the washed pellets, use the following guidelines. (1) An expression level of 1% corresponds to ~1 mg recombinant protein per 1 g wet cells. (2) The recovery of highly aggregated recombinant protein in the washed pellets is ~75% that originally present in the cells. (3) About 60% of the total washed pellet protein is recombinant-derived. Thus, if 50 g cells is processed and the expression level is 5%, the washed pellets contain ~200 mg recombinant protein.

    The total amount of recombinant-derived protein in washed pellets can be directly determined by measuring the total protein concentration or by analyzing the washed pellets via SDS-PAGE (see Support Protocol and UNIT 10.1) to determine the proportions of the protein constituents.

    For gel-filtration purposes, the pellets from 50 g wet weight E. coli cells are solubilized with 40 to 50 ml extraction buffer (see Basic Protocol 2); the concentration of recombinant protein in the extract will be 4 to 5 mg/ml. For direct protein folding (UNIT 6.5), the pellets are extracted with 100 to 200 ml buffer, and the concentration of recombinant protein 1 to 2 mg/ml. If the washed pellet is heavily contaminated with outer cell wall and peptidoglycan material, the extract must be diluted further with extraction buffer (usually 1:1 to 1:3) to reduce the viscosity before it can be used for chromatography.

11. Centrifuge the suspension 1 hr at 100,000 × *g* (30,000 rpm in Ti45 rotor in a Beckman Optima XL-90 ultracentrifuge), 4°C.

    For volumes <250 ml the Beckman 70Ti rotor (capacity 6 × 39 ml) can be used at 32,000 rpm (~100,000 × g).

12. Carefully pour off the supernatant from the pellet. Filter the supernatant through a 0.22-µm syringe filter attached to a 20-ml disposable syringe.

    The filter removes unpelleted large cell wall debris that will clog most chromatography columns.

13. Use the clarified inclusion body extract for preparing folded protein (*UNIT 6.5*) or purify further by gel filtration (see Basic Protocol 2).

    The extract can be stored at –80°C until required. Freeze in plastic (or polyethylene) containers rather than glass. Divide sample into 10- to 20-ml aliquots instead of freezing in one large lot and fill containers to only 50% to 75% capacity.

MEDIUM-PRESSURE GEL-FILTRATION CHROMATOGRAPHY IN THE PRESENCE OF GUANIDINE HYDROCHLORIDE

BASIC PROTOCOL 2

Washed, extracted pellets (see Basic Protocol 1) contain >50% recombinant protein and are used as the starting material for purification of the protein of interest by gel-filtration chromatography. Superdex 200 gel-filtration medium, which allows high flow rates, is washed and packed into a column. The column is equilibrated at 4°C and the sample is applied.

Assay of column fractions by gel electrophoresis in the presence of SDS is complicated by the fact that guanidine·HCl forms a precipitate with SDS. Therefore, preparing samples

BOURNS / CENTRAL UNIVERSITY LIBRARY

for gel analysis involves selective precipitation of protein from guanidine·HCl prior to SDS-PAGE (see Support Protocol). The purified (or partially) purified protein is used as the starting material for procedures (e.g., *UNIT 6.5*) in which the denatured protein is folded into a native and biologically active structure.

Materials

Gel-filtration medium: Superdex 200 PG (preparative grade; Pharmacia Biotech)
5% (v/v) ethanol
Gel-filtration buffer (see recipe)
Guanidine·HCl extract of *E. coli* cells containing the protein of interest (see Basic Protocol 1)

4- to 6-liter plastic beaker
Chromatography column: Pharmacia Biotech XK 16/100, 26/100, or 50/100
Packing reservoir: Pharmacia Biotech RK 16/26 (for 16- and 26-mm-i.d. columns) and RK 50 (for 50-mm-i.d. column)
Chromatography pump: Pharmacia Biotech P-6000 or P-500
Injection valve (to select between sample loop and pump)
UV monitor and fraction collector
Sample loop (volume determined by size of column)

NOTE: The various components of the chromatography system (pumps, valves, monitors, and sample loops) listed separately above are supplied as components of the BioPilot chromatography system (Pharmacia Biotech), which is used to run the XK 50/100 column. The smaller XK columns (2.6 and 2.5 cm i.d.) are run using the FPLC chromatography system (also from Pharmacia Biotech), which is designed for small- to medium-scale work. For further details on this equipment see the manufacturer's literature (e.g., *Process Products*, Pharmacia Biotech).

NOTE: Perform steps 1 to 11 at room temperature. After the column is packed, equilibrate and elute at 4°C.

Pack the column

1. Wash the gel-filtration medium in a large plastic beaker with 5% ethanol. Let the medium settle and adjust the volume of liquid to give a gel slurry concentration of 65% to 75%.

   The XK 16/100, 26/100, and 50/100 columns are 100 cm long and have inner diameters of 16, 26, and 50 mm, respectively. Hence, for an XK 50/100 column, column volume = radius (2.5 cm)^2 × 3.1416 × bed height (97 cm) ≅ 1900 ml, and ~2 liters preparative-grade Superdex 200 is required. To pack this column, the gel medium is suspended in 5% ethanol to give a total volume of 3 liters which corresponds to ~70% gel slurry (it should be noted that the RK 50 reservoir has a capacity of 1 liter, so the 3 liters of gel slurry can be poured in a single operation).

2. Fix the chromatography column in an upright position, using a level to adjust the position. Attach the packing reservoir.

3. Add sufficient 5% ethanol to displace the air from a few centimeters of the bottom of the column. Clamp off the bottom of the column.

4. Gently mix the gel-filtration medium in the plastic beaker to an even slurry of 70% medium suspended in 5% ethanol.

5. Degas the suspension 5 to 10 min using a vacuum flask and laboratory vacuum.

   The ethanol is included to reduce the surface tension and density of the solvent, thus allowing air bubbles that form to rise to the surface more quickly.

PCU IASI / CENTRAL UNIVERSITY LIBRARY

6. Carefully pour the slurry of medium into the column, introducing material along the side of the column to avoid creating air bubbles.

7. Let the column stand 5 min and then unclamp the bottom of the column.

8. Attach the chromatography pump to the packing reservoir and pump 5% ethanol (degassed) into the column at an appropriate flow rate (based on manufacturer's instructions). Pack the column at a pressure greater than the pressure at which the column will be run (up to twice as high), but not greater than the maximum pressure rating of the column.

   The XK 50/100 column (rated to 0.5 MPa) is packed at ~20 to 30 ml/hr and ~0.4 MPa.

9. After the medium has settled, turn off the pump and close the bottom of the column. Pipet fluid from the reservoir and remove the reservoir.

   Once the column has been packed, be careful to prevent air from entering the column bed. Air will disturb the bed and reduce the column separation resolution.

10. Attach the column top adapter to the column. Place the top of the adapter onto the top of the packed medium and gently compress the medium.

11. Reattach the pump to the column and wash the column with water at a flow rate that will generate the maximum pressure to be used. If the medium continues to settle, readjust the top adapter to maintain a firm fit against the gel.

From this point onward, perform all steps at 4°C.

Equilibrate the column

12. Equilibrate the column with at least 1 column volume of gel-filtration buffer.

    Although the proteins were extracted with buffer containing 8 M guanidine·HCl (see Basic Protocol 1), the gel-filtration buffer contains only 4 M guanidine·HCl. The concentration is reduced to allow faster flow rates and for reasons of economy. Most proteins remain unfolded at the lower guanidine·HCl concentration. If, however, the protein elutes in an anomalous manner (e.g., in more than one peak or at an elution position not consistent with its size), and assuming there is adequate reducing agent present, then try increasing the guanidine·HCl concentration in the gel-filtration buffer.

13. Measure the actual flow rate while running the column at a flow rate that generates a back pressure about one-half of that generated when packing the column (step 8).

    For an XK 50/100 column packed using Superdex 200 at 0.4 MPa, a running pressure of ~0.2 MPa is used, which generates flow rates of 5 to 10 ml/min that are equivalent to linear flow rates of 15.3 to 30.6 cm/hr. The linear flow rate equals the flow rate (ml/hr)/cross-sectional area (cm^2). At these flow rates it takes between 3 and 6 hr to complete the chromatography.

14. Connect tubing from the end of the column to the UV monitor and the fraction collector.

Apply the sample

15. Load the sample loop with the guanidine·HCl extract to be separated.

    Avoid loading a sample volume >5% of the total column volume; the optimum sample size is 2% (~40 ml for the XK 50/100 column). The sample consists of washed pellets extracted with guanidine·HCl (see Basic Protocol 1). A sample size of 40 to 50 ml is usually derived from ~50 g wet weight cells. With smaller sample sizes, use columns with proportionally smaller diameters (e.g., XK 16/100 or 26/100 columns). If pur-

BOSTON UNIVERSITY MEDICAL CENTER LIBRARY

chase of only one column is possible, a 2.5 × 100–cm size is a good compromise for variable sample loading.

16. Monitor column effluent with the UV monitor and collect fractions with the fraction collector.

    For an XK 50/100 column, collect 15- to 20-ml fractions in 16 × 20–mm culture tubes.

    The eluent from the column is usually monitored at 280 nm or, if the protein has a particularly low extinction coefficient, at 230 nm (guanidine·HCl strongly absorbs below 225 nm). For an XK 50/100 column, fractions need only be collected after ~500 ml of elution. The excluded volume (void volume) is ~570 ml. Run one column volume (1900 ml) to ensure all of the load material is eluted from the column.

17. Prepare the fractions to be assayed for SDS-PAGE (see Support Protocol and *UNIT 10.1*).

SUPPORT PROTOCOL

PREPARATION OF SAMPLES CONTAINING GUANIDINE HYDROCHLORIDE FOR SDS-PAGE

Because guanidine·HCl forms a precipitate with SDS, it is necessary to remove the former before carrying out SDS-PAGE. Protein in column fractions is separated from guanidine·HCl by precipitation using 90% ethanol (Pepinsky, 1991).

Materials

Sample containing the protein of interest
100% ethanol, 0° to 4°C
1× SDS sample buffer (*UNIT 10.1*)

Gilson Pipetman (Rainin Instrument)

Additional reagents and equipment for gel electrophoresis (*UNIT 10.1*)

1. Pipet 25 µl sample containing the protein of interest into a 1.5-ml microcentrifuge tube.
2. Add 225 µl cold (0° to 4°C) ethanol to the sample in the tube.

   The final ethanol concentration is 90% by volume.

3. Mix the sample and ethanol well. Chill 5 to 10 min at –20°C or colder (e.g., –80°C).
4. Microcentrifuge the sample 5 min at maximum speed (~15,000 × *g*), 4°C. Carefully withdraw the supernatant and retain the pellet.

   The pellet may be difficult to see. Be careful not to draw the pellet out of the microcentrifuge tube with the supernatant.

5. Suspend the pellet with 250 µl cold 90% (v/v) ethanol. Mix thoroughly using a vortex mixer.

   The 90% ethanol is made by mixing 225 µl ethanol and 25 µl H_2O.

6. Microcentrifuge the sample 5 min at maximum speed, 4°C. Carefully pipet off the supernatant and suspend the pellet in 25 µl of 1× SDS sample buffer.

   Some proteins are more difficult than others to suspend from an ethanol precipitate. Electrophoresis sample buffer containing 8 M urea is helpful for such proteins (UNIT 10.1). Sonication with a microtip probe can also be used to disperse the sample. A volume of sample buffer >25 µl may be required in this case (e.g., 50 µl), and great care must be taken to prevent foaming of the sample caused by excessive sonication power.

RCU IASI CENTRAL UNIVERSITY LIBRARY

7. Heat the sample 3 to 5 min at 90° to 100°C. Load on an SDS-polyacrylamide gel (*UNIT 10.1*).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see APPENDIX 2E; for suppliers, see SUPPLIERS APPENDIX.

Extraction buffer

50 mM Tris·Cl, pH 7.0
5 mM EDTA
8 M guanidine·HCl (764 g/liter)
5 mM DTT (770 mg/liter)

If the buffer is cloudy, filter through a 0.45- to 0.5-μm filter (the solution should be clear if high-quality guanidine·HCl—e.g., ultrapure grade, ICN Biomedicals—is used; see *APPENDIX 3A*). Buffer can be stored minus DTT at least 1 month at 4°C.

Gel-filtration buffer

50 mM Tris·Cl, pH 7.5
4 M guanidine·HCl (382 g/liter; ultrapure, ICN Biomedicals)
5 mM DTT (770 mg/liter)

Buffer can be stored minus DTT at least 1 month at 4°C. Filter (as for extraction buffer; see recipe) and degas before use.

Higher concentrations of guanidine·HCl (up to 8 M) may be required for some proteins (see comment at step 12).

Lysis buffer

100 mM Tris·Cl, pH 7.0
5 mM EDTA
5 mM DTT (770 mg/liter)
5 mM benzamidine·HCl (780 mg/liter)
Prepare immediately before use

The Tris·Cl and EDTA are diluted from concentrated stock solutions. The other components are added to the diluted buffer before use.

Wash buffer

100 mM Tris·Cl, pH 7.0
5 mM EDTA
5 mM DTT (770 mg/liter)
2 M urea (120 g/liter; ultrapure, ICN Biomedicals)
2% (w/v) Triton X-100 (20 g/liter; Calbiochem-Novabiochem)

Add DTT, urea, and Triton X-100 to the other components directly before use. Prepare this buffer in two forms: one with and one without the urea and Triton X-100 (the latter for use in Basic Protocol 1, step 9).

COMMENTARY

Background Information

The decision of whether to work with insoluble recombinant protein or to put more effort into generating soluble protein (e.g., by modifying the expression vector or changing the host strain and fermentation conditions) can be dictated by the nature of the protein. A small protein (10 to 17 kDa) with only one or two cysteine residues might be expected to fold in reasonable yield from extracted inclusion bodies. Larger proteins (>25 kDa) with many cysteine residues may be more problematical, and lower folding yields can normally be expected. In the latter case, if only small amounts of material are needed then yield is not such an important issue.

It should be emphasized that, unless proved otherwise, a protein folded from insoluble inclusion bodies can be expected to have the same structural and conformational integrity as the same protein directly purified from soluble extracts (also see *UNIT 6.1*). It is similarly true that a purified soluble protein can be denatured and renatured (reversible denaturation) without structural or conformational modifications (reviewed by Anfinson, 1973; Ghelis and Yon, 1982).

How inclusion bodies are formed

Inclusion bodies are noncrystalline, amorphous structures; however, there is some evidence that the constituent densely packed proteins may have nativelike secondary structures (Oberg et al., 1994). This suggests that the aggregates are formed by the association of partially folded protein or so-called folding intermediates. Furthermore, the aggregation appears to take place late, rather than early, in the folding pathway.

Although inclusion body formation and its prevention are of great academic and commercial interest, the pragmatic situation is clearly summarized by Seckler and Jaenicke (1992), who state: "That inclusion bodies are aggregates of otherwise intact polypeptides in nonnativelike conformations has been proven repeatedly by the successful refolding of active proteins after dissociation of the aggregates by chemical dissociation." It must be noted that the work of Oberg et al. (1994) does not invalidate this statement. It is simply a matter of terminology: the protein in aggregates may have nativelike secondary structures, but compared with soluble folded protein it must still be considered nonnative.

The propensity of a protein to form inclusion bodies is not related to the presence of sulfhydryl residues, as proteins without sulfhydryls still form such aggregates. Furthermore, where carefully studied, it has been found that aggregates derived from proteins that in their native state contain disulfides consist mainly of reduced protein (Langley et al., 1987). This also supports the view that inclusion bodies are not aggregates of completely unfolded protein because, if so, random disulfide bond formation would occur despite the reducing environment of the *E. coli* cytoplasm. Regardless of the sulfhydryl state in the aggregates, once the protein has been solubilized, reducing agents must be included to prevent the formation of nonnative disulfide bonds.

Extracting inclusion body protein

Proteins are extracted from inclusion bodies using strong protein denaturants. Protein denaturation can be induced by the following solvent conditions or reagents.

1. *pH.* Protein denaturation occurs because of the ionization of side chains. Generally, proteins retain less residual structure (are more denatured) when exposed to high pH (e.g., >10.5) compared to low pH (<4.5). Acidic or basic pH may be used in conjunction with urea or inorganic salts. An example of acidic pH extraction is given in *UNIT 6.5*.

2. *Organic solvents.* Examples of organic solvents include ethanol and propanol. Generally, proteins are not completely unfolded in these solvents. Organic solvents are infrequently used for the primary extraction of inclusion bodies but can be useful cosolvents to enhance protein folding (Chang and Swartz, 1993).

3. *Organic solutes.* Examples of organic solutes include guanidine·HCl (used at 6 to 8 M; effectiveness independent of solvent pH but temperature-dependent) and urea (used at 6 to 9 M; effectiveness modulated by pH, ionic strength, and temperature). Organic solutes are the most versatile and most commonly used denaturants for solubilizing inclusion bodies. The denaturing power of guanidinium salts increases in the order $Cl^- < Br^- < I^- < SCN^-$.

4. *Detergents.* The most common examples of protein-denaturing detergents are sodium dodecyl sulfate (SDS, an anionic detergent) and cetyltrimethylammonium bromide (CTAB, a cationic detergent). Both are effective protein denaturants, but they are not nor-

mally used to solubilize inclusion bodies as they interfere with recovering folded protein in reasonable yields (e.g., see van Kimmenade et al., 1988).

5. *Inorganic salts.* Salts at high concentration (>1 M) often denature proteins. The denaturing power increases in the following order for anions: $SO_4^{2-} < CH_3COO^- < Cl^- < Br^- < ClO_4^- < SCN^-$; for cations, the order is $(CH_3)_4N^+$, NH_4^+, K^+, $Na^+ < Li^+ < Ca^{2+} < Gdn^+$ (reviewed by von Hippel and Schleich, 1969). The organic guanidinium ion (Gdn) is included for comparative purposes. Salts have not been widely used for solubilizing inclusion bodies. On the other hand, they are frequently used for selective extraction of extrinsic membrane proteins and in principle should be useful for preextracting inclusion bodies. Denaturing salts such as KSCN or LiBr are sometimes referred to as chaotropes (tending to disorder).

6. *Temperature.* Thermally induced extraction is rarely used as it often results in irreversible protein denaturation (Zale and Klibanov, 1986). However, denaturants such as guanidine·HCl and urea are more effective at elevated temperatures (e.g., 37° to 60°C). Care must be taken when heating urea solutions because of the increased rate of cyanate formation, which will covalently modify amino groups on the protein, especially at pH >6.

A comparison of some protein denaturants and their relative effectiveness is described by Pace and Marshall (1980, and references cited therein). Monera et al. (1994) provide an explanation of why guanidine·HCl is usually two to three times per mole (2- to 3-fold) more effective than urea at unfolding proteins. The mechanism of protein denaturation is reagent-specific; this topic has been reviewed by Tanford (1968), Ghelis and Yon (1982), and Creighton (1993).
